There are, however, in France, great establishments—such as those of M. Voruz, at Nantes—engaged wholly in bronze and brass-founding, and with special departments for artillery, for casting for mechanical purposes, and for statues and other objects of architecture and of art; all being, though of course with the usual fluctuations of trade, kept constantly at work. We are ignorant of a single like establishment in Great Britain. Paris is, however, the great head-quarters of fine-art brass and bronze-casting, and practically supplies the world with its productions.

We view, as out of this trade altogether, the very numerous, and, in a trade-sense, important brass-foundries of Birmingham and its neighborhood, engaged upon small objects for house or domestic or other use, and which profess to have more or less of ornamentation, but certainly have but small pretensions to art, in any worthy sense. Nor do we refer to Japanese bronze and brass work, further than just to remark, that while objects of considerable, some of great, antiquity brought thence formerly by the Dutch, and more recently by ourselves and other European nations, prove that at some anterior epoch, artistic bronze manufacture had reached a very noble perfection, and great peculiarity and often beauty of treatment in design, more modern examples equally prove that the art has greatly deteriorated amongst that wonderful people, or that we now receive from them none of their best examples of art.

No English person who has been a day in Paris can have failed to be struck with the profusion of bronzes in the public ways, in the buildings public and private, and in the shop windows. Bronze-casting is, in fact, a great industry there. There are probably not less than three hundred houses engaged in the trade in one way or other; but of these there are no more than perhaps about fifty who are actual manufacturers, and of these again not more than about twenty who stand in the first rank, of ability and eminence, either as conducting some one or more special branches of the *bronzes des beaux-arts* trade, or the whole of them. But although thus the finished objects of the Parisian bronze-founder arrest the eye and glitter before us at every step upon the Boulevards or in the Palais-Royal, next to nothing is known generally, not even to the technical or metallurgically-skilled visitor to Paris, of the establishments whence these beautiful and costly objects issue, or of the apparatus and methods by which they are produced. They are, in fact, sealed, rigidly shut against all intruders, and for many good and sufficient reasons, which do not admit of being regarded as the mere offspring of narrowness, timidity, or jealousy. One only we need mention. The workmen are, in each of several classes, specialists, in a sense the most absolute, and French employers have found that unworthy and unscrupulous means to detach these men and bring them elsewhere, have been but too often practiced by those to whom the grace of *entrée* may have been accorded.

We have heard, though we do not at all intend to suggest, that, in this way, fine-art bronze-casting in Belgium and in Germany has been very much advanced by the introduction of French artisans.

In Italy most of the workmen, in such establishments as that of Signor Clement Papi, which produced the largest bronze statue, that of the David of Michael Angelo, in 1867 at Paris, are natives; but we believe this is not the case in Prussia, Austria, or Russia.

So far as we are aware, no literature exists which treats in a detailed or practical way of the methods and apparatus of the fine-art bronze-foundry. We shall find none whatever where we might have expected it, viz: in the volumes of Reports of the French Imperial Commission of the Exhibition of 1867, or, indeed, in the reports of any preceding one. The reporter for 1867, on class 22 (Vol. III, of the collected reports) was M. Barbadienne, the man who perhaps, above all others, *could* have given us a complete and invaluable treatise upon the technicalities of this manufacture, in which he has so long and so conspicuously led the advance. We look for any such details in vain; not that we imagine M. Barbedienne felt the slightest desire or ground for reticence, but that the space assigned him in these volumes as a reporter was far too restricted to admit of his dealing with more than mere generalities; indeed, the whole 500 pages of Vol. III might prove less than enough to enable, one at once so skilled in every detail, æsthetic and technical and so enthusiastic, to pour forth the treasures of his knowledge upon this speciality, in which he so admittedly leads.

Where no literature exists, therefore, a sketch may be accepted as a not unwelcome installment. Such we are enabled to give, the writer having been recently accorded by M. Barbedienne himself the unusual and special favor of the unreserved examination of his noble foundry and manufactory at Paris.

There are, no doubt, half-a-dozen fine-art bronze-foundries in or about Paris, the description of any one of which would prove interesting. That, however, of M. Barbedienne stands amongst these *facile princeps*, and indeed is not one, but, so to say, a congeries of special manufactures. The works are situated in the Rue de Lancry, at not a very great distance from the well-known "show shop" of bronzes, as our homely phrase is, No. 30 Boulevard Poissonnière. It is, however, happily placed, though still upon the edge of that quarter of fashion, traffic, and pleasure, also upon the border of that wonderful north-east quarter of Paris, which, like our own north-east of London, is the seat of so many of its myriad industries, and which, as respects the French capital, is a *terra incognita* to ninety-nine out of the hundred Englishmen who visit that city, or even reside in its fashionable quarters.

Entering from the street, we pass through a range of offices, waiting-rooms, packing-rooms and stores, and find ourselves crossing a yard, and at once in the large bronze-foundry.

The establishment comprises, in fact, the following departments if we may not almost call them distinct manufactories:

1. The bronze-foundry and its accessories.
2. The chasing-shop—*galerie des ciseleurs*.
3. The shops for the production of models, and for the completion of a large number of these in the permanent material bronze.
4. The marble work; a complete establishment for the working, both by machine tools and by the sculptor's hand, of all sorts of marbles, onyxes, and other fine and hard minerals.
5. The shops for mounting of Carcel lamps and other objects of artistic bronze work in combination with porcelain, glass, etc.
6. The enameling shops, in which that peculiar form of "*émaux cloissonnés*" which, dating from Byzantine art originally, had been lost to practice for ages in Europe, though always employed in China and Japan, and were revived in France by M. Legost, in 1855, and greatly extended by M. Barbedienne.
7. The "*atelier*," in which the delicate and beautiful machinery of M. Collas is worked for the automatic reduction or enlargement of solid forms.

This machinery is constantly employed in the production of new models for bronzes, etc., whether figures or bas-reliefs, etc., and of every size. It constitutes, as M. Barbedienne has himself affirmed, the right-hand of the bronzist, enabling him not only to reproduce the forms of ancient art with rigid exactitude, but to copy them equally so to any scale, and at an extremely small cost.

Were it not for this machine-tool, it would be impossible, at any reasonable prices, for M. Barbedienne to quote in his catalogue sometimes as many as eight different sizes for the same reproduced antique statue, and to have at command five or six sizes in bronze of nearly all the celebrated statues, ancient or modern, which enchant the world.

M. Collas' machinery gained him, and we believe very justly, the grand medal of honor at Paris, in 1855. Its rudiments, however, are very ancient, and to be found in many an old book on turning; and in reality we believe there is little doubt but that all which M. Collas has effected was done, and thoroughly well done, by Cheverton in London as early, perhaps, as 1830; as those who have seen, or are happy enough to possess, specimens of his matchless reproductions to a reduced size, in ivory, of the antique bust of Clytie, must be aware. Cheverton, however, worked his machine in secret in his chamber, and would not divulge its details, and we believe died without having ever fully and publicly claimed to have been its perfector.

What degree of similarity there may be between both we cannot say, but all machines of this class in reality depend upon the use (more or less implicated, of course) of a lever, the ratio of whose arms is variably at will, one end of which carries a dumb point which traverses, in closely and equally adjacent parallel lines, over the contour to be copied; while the other end, guided by that, carries the revolving or other cutting tool which removes the brute matter from the mass, to be formed into the reduced, or equal, or enlarged copy, and can remove no more.*

8. Besides all these there are "mounting shops," where the bronze pieces are connected, either with precious marbles or stones, or by "*menuisiers-ébénistes*" with fine cabinet work.

Subsidiary to all these there is a grand gallery or store, for porcelains, Indian, Japanese, French, English, etc., to be employed for divers ornamental ends in combination, and a whole tribe of small shops for the preparation and repair of tools, etc., etc. We need scarcely say amongst these are "drawing shops," artists' studios, in fact, where the imaginative brain labor that inaugurates much that follows, is in full play on the part of architectural and sculptural draughtsmen, and other artistic "*coopérateurs*" of the establishment.

Let us return to the foundry and its adjuncts, of which we can describe much to interest our readers, without any breach of the confidence reposed in us, as visitors to these famous works.

The foundry is a very large rectangular brick building, whose sides are about twice the breadth. It is lighted by ample skylights in the roof, and we at once notice the perfect cleanness of the walls and roof, and the nice clear pearl-white with which the brick of the former is colored, so as to afford the best light without distress to the eye. There are no piles of rubbish about, neither spare-boxes, nor unused models; all is orderly, a picture of neatness.

The floor, with the exception of some gangways, is of loamy sand, and ready in heaps beside each moulder.

The greatest proportion of the work being small, or very small, so the whole (nearly) of the moulding work is done on benches.

These occupy a large proportion of the whole area, and are arranged transversely to the length of the building in parallel ranges, with an axial gangway passing right through, and dividing them along the center. Each bench is double, *i. e.* two benches and two sets of moulders face each other at work. Each bench varies in width from $3\frac{1}{2}$ to perhaps 5 feet; and the mid-line of separation between the opposite benches of the same double bench is occupied by a raised division, with a low table or shelf on top to hold tools.

By far the greater portion of the work is moulded "in dry sand," the large statues being in true "loam work," but "green sand" moulding for small, plain, or unimportant objects is also largely practiced.

At one side of the "*salle*" is the place where the sand is prepared, mixed and damped. The sand employed is of two qualities, one being of a deep brown color, and very loamy; the other of a very light yellowish-white, with more yellow particles *parsemé*. Both are obtained at Fontenay des Roses, not far from Paris to the northwest. The two sorts are mixed, first, by interstratefying them in alternate layers in heaps, the relative thicknesses depending partly on the class of work the sand is being prepared for.

These zebra-striped heaps are then cut down with the shovel, and the whole set between a pair of very fine set horizontal cast-iron rollers. The sand is finally, after being damped to the right degree, sifted, and so handed over to the men. The "*chassis*" or moulding-boxes are all of cast-iron, very carefully fitted together, and with well-planed edges. We did not see a single wood-box* (so common even now in British brass-foundries), nor any makeshift of any other sort about the establishment.

Wood patterns or models also are but little employed, except for objects to be finished in the lathe. The models are chiefly of bronze, carefully chiseled or chased up, and given a dull brownish-grey sort of "patina," which seems to enable them to part from the sand with very great cleanness. Plaster casts, fusible metal, wax, and even occasionally porcelain or glass come into play as models also. All the bench moulding-work is of a character demanding great care, dexterity, and patience. The latter quality, as well as steadiness of hand and perfection of vision, find their greatest demand with the moulders who are engaged in casting objects which are to form the basis for the *émaux opaques et cloisonnés*.

* Blanchard lathe.

* "Practical mechanic's" name for "flask."—Ed. V. N.'s Mag.

Our readers generally are, no doubt, familiar with the character of these from seeing the like objects exhibited in Chinese and Japanese collections. The design, always of a stiff and conventionalized character, is outlined, as it were, and its distinct portions divided by very thin walls of bronze, mere lines almost, which rise square up from the general surface of contour of the object, and to a height equal to the depth of the intended coat of enamel, which is very thin, not more even than a millimeter, seldom more than half as much. Thus, in fact, the enamel when baked in, is held fixed in so many shallow bronze-surrounded cells, the dividing and adjoining edges of which are polished off bright, at the same time that the enamel is ground off to a uniform surface. This little digression may serve sufficiently to explain the nature of *émaux cloissonnés;* and into the details of the compositions of the enamels themselves, and how applied and completed, we do not here purpose entering.

It will thus be seen that the very utmost importance attaches to casting these little *cloisons*, or cells, perfect; any morsal of bronze improperly filling a portion, however slight, when cast, has to be cut out by hand, and at some risk of damaging the thin low wall of the *cloison* itself.

It is almost painful to watch the lynx-eyed patience with which the moulder of one of these objects—say, a huge vase of three feet in hight, covered all over with thousands of these cells—finishes each, with minute almost microscopic hand tools, after he has "drawn" the bronze pattern. The value of this is represented mainly by the money consumed in payment for the design, the original wax and plaster model, and the casting and hand-finishing of this workable bronze pattern; such patterns are laid aside on cushions, and kept covered carefully.

We shall not devote space to describing the considerable system in operation for the organization, registration, preservation, cleansing, and return into store, of the innumerable patterns. The law of copyright, which in France is far more protective and precise than it is with us, has greatly relieved such men as Barbedienne of one of their anxieties, viz: that of having their design stolen, or their models bought for patterns by others; still, the *chefs d'œuvre* are guarded with care.

The facing sand of the moulds, whether dry or green, is prepared with a mixture of charcoal dust and of potato starch, or of wheaten flour of the very finest grinding. In the preparation of these each moulder takes his own way, and there appears to be as much whim and variation here, as amongst iron-moulders. Sand cores, amply hollowed for air, are employed for all hollow objects, not of large size or not cast in loam; for the latter, the cores are also of loam. In statue-casting it is deemed of high importance to the final perfection of form when cast, that the thickness of the casting should be perfectly uniform. This arises chiefly from the great contraction in cooling (from 1 to 2 per cent) of bronze, and the prolonged state of plasticity through which it passes between the liquid and solid states. Hence, if there be thick parts as well as thin, the latter solidify so completely before the former that the thick parts get more or less distorted. The distortion may be utterly invisible to the undisciplined eye, but that of the artist-workman here readily detects and finds fault with a change of form in the muscles of a "*Discobalus*" or a "*gladiator*," or in the voluptuous rounding of the limbs of a *Vénus accroupie*" or "*de Milo*," which the world at large cannot discern.

The contraction of cooling is found to augment in ratio, with the size of the object cast, being greatest in large statues. For all these reasons, the utmost care and some very refined, though simple, methods are employed to ensure that "the core" shall be in form precisely similar to the exterior of the statue or figure, and that it shall be placed and fixed in the mould with rigid concentricity. It is the opinion of M. Barbedienne, which he has expressed in his Jury Report (Class 22) of 1867, that wheaten flour is not so good a facing material as charcoal dust; but he deems that much remains to be learnt as to the best material for facing bronze sand-moulds, and hesitates not to say that no moulder now-a-days succeeds in attaining an equally *fine and uniform granulation* of surface as was habitually produced by some of the great bronze-founders of older days, such as Richard, the Ecks, Durand, and the brothers Keller, who cast so much for Louis XIV.

It is also worthy of memory how fully M. Barbedienne insists upon the primary importance of perfection in the moulding and casting. Most persons would say that an object which was to pass into the hands of the "chaser," or *ciseleur*, might be cast as rough as we please, and yet all its faults be remedied in the metal-sculptor's hands. Skilled experience says no; it even goes so far as to say, if the work come out of the sand perfect, the less the "chaser" does to it afterwards the better; and, in fact, M. Barbedienne boldly attributes the matchless beauty of many antique, or even middle-age bronzes, to the fact that in these, the same mind, eye and hand carried through the entire process, from the conception of the model to its completion, thence to the moulding and casting, and finally to the chiseling and dressing, and to complete finish.

This seems to have been true in some cases at least, if not in general. The exquisite bronze statuette of the young man, found about five years since at Pompeii, which has been called, though on no sufficient evidence, "the Listening Hunter," and which is undoubtedly one of the finest reproductions in the world, to reduced scale, of the youthful male form, as well as several of the great *relievo* castings of mediæval Italy, in gates and well ("*pozzi*") curbings, are cases in point.

But to return; at the end of the foundry, furthest from the entrance, are the furnaces, the stove for drying the moulds and cores, of which we need say nothing but that it is heated by the waste furnace-heat, and a large wrought-iron jib crane for pitting and unpitting boxes in which large objects are cast.

The bronze for all moderate-sized objects, say up to 250 kilos., is melted in clay crucibles, which are made in the neighborhood of Paris, and hold about 30 kilos. each. These are not extremely refractory, but stand three or four meltings.

There are eight crucible furnaces, in form very much that of the ordinary brass furnace, but differing from usual practice, in England at least, in that they are not wind furnaces, but are fed with blast, from a small fan (about 20 in. diam.), driven by a strap from the engine of the "*marbrerie;*" the fuel is coke, and the advantages seem to be patent of this arrangement. The metal is "brought down," *i. e.* melted, very much faster, the "heats" can be repeated much more rapidly, and the consumption of coke is greatly less than with wind furnaces. Then again, when the crucibles are about to be "drawn," the blast is thrown off, and there is much less flare and heat to be endured by the man who lifts them out. The tops of these furnaces are of cast-iron, the covers of iron-bound square fire-tiles, and the tops are about 22 in. above the floor level.

The large air-furnace is fed with dry wood fuel, and will melt upward of 1,000 kilometers.

In older times statues were always cast in a loam-mould, put together piece by piece in the excavated pit, and, as fitted in place and jointed up, the pit was rammed up round them. This was but a make-shift mode, and had several serious evils: the mould never could be dried with perfect uniformity; and even when dry, it stood so long in the pit while being got ready, that it imbibed moisture anew, and hence so many "mis-casts" of old. Under the heavy head of liquid bronze, too, the ramming-in of the pit sometimes proved soft and deceptive, so that here or there the walls of the mould partially bulged, and the casting was either lost or damaged.

All M. Barbadienne's statues or large objects are cast therefore in cast-iron flasks or boxes, so that the pit is what iron-founders call a "naked pit," *i. e.* no ramming-up is practiced.

A "pool" or reservoir of sand with charcoal facing, is employed for all large castings, into which the contents of the crucibles are "teemed," or into which the air-furnace is tapped. When the full quantity of metal is in the pool, an iron conical plug, which had been inserted into and stopped the main "gait" or "*coulée*," is drawn up, and the metal enters the mould.

It passes off (as overplus) by "rising heads," as in cast-iron moulding, and "the gas is fired" at these, by a lighted torch in the same way. From the low temperature of the liquid bronze, however, as compared with cast-iron, but a small volume of gas is evolved from either moulds or cores.

The head of surplus pressure employed is always very small, for fear of distortion; a practice exactly the reverse of that of bronze-gun founding, where the "*masselet*" or "rising head" is often nearly as long as the gun itself above its muzzle, which is uppermost in the mould. It may be very much doubted, or even on plausible grounds contested, whether any advantage is obtained by these very long "gun heads," and whether some positive evils in the increased segregation of the alloy be not thus introduced. Bronze-gun founding, however, is now, in these days of huge wrought-iron artillery, somewhat an art of the past, it may be said. We must remember, however, that Prussia is returning to bronze rifled field-guns, and that our new rifled Indian artillery is also to be of bronze.

The metals employed by M. Barbedienne for his bronze are very pure "tile pitch" copper, and English or Straits tin, also of best quality. The copper is usually South American, again melted in France, purified by "liquation," and run into small pigs of about the size and form of ours known as "Best selected copper."

A proportion of bronze from "gaits and runners" is usually added, but the composition of this is *quam prox.* already known and constant, and its material is unadulterated, so no mischief can arise. No *old material*, whether copper, bronze or brass is ever employed; and the *directeur du travail*, who so intelligently and politely showed us round the works, and explained their methods with the lucid brevity so characteristic of the higher *contre-maître* of France, expressed his opinion that it was impossible ever to cast a first-rate statue or relief, especially of large size, from old bronze guns, or other old material of variable composition. He instanced many proofs of this; and, undoubtedly, the porous bad castings of the reliefs of the Napoleon Column in the Place Vendôme, of the statue of Desaix, etc., at Paris, and of our own Trafalgar Square lions seem to sustain this view.

That bronze ornamentation is not more widely diffused in Europe generally, and that it is so prevalent in France, arises from two main causes. Fiscal or custom-house regulation of absurd severity in the case of all the European nations; and on the part of the United States, and as respects ourselves, want of diffused good taste or perception of beauty in form, either in the interior or exterior of our public or our private buildings or national monuments.

For 100 kilos. of bronze, on entering the frontiers of each of the following nations, the duties are thus:

	Bronze.	Bronze gilded.
Russia	377 francs	470 francs.
Austria	250 "	250 "
Spain	155 "	155 "
France	20 "	100 "
Italy	17.17 "	100 "
Switzerland	16 "	100 "
Prussia	13.10 "	112.50 "

In United States 350 francs on 1,000 francs value.

Belgium	100	"	"	"	"
Holland	50	"	"	"	"

England and Portugal alone admit bronzes free.

The *bizarrerie* of these figures forms a curious commentary on the wisdom of finance ministers everywhere.

We must, however, reserve to a future article some further remarks upon these works for bronze, and upon ornamental zinc and iron castings, which follow humbly in its steps.

SEA-GOING TURRET-SHIPS.

From "The Practical Mechanic's Journal."

The completion, at Chatham, of the Monarch affords a fitting opportunity for a few remarks on sea-going turret-ships. It is well known that the earlier turret-ships of our navy—the Royal Sovereign and Prince Albert—are really coast-defense ships, since they have only a minimum of sail-power, and are so badly supplied with coal as to limit very narrowly their steaming capability; for coast and harbor defense they will, however, prove useful, should their services ever be required. Besides these, we have in our navy the far-famed Scorpion and Wivern, built by Messrs. Laird during the American war, and purchased by the Government after they had been for some time in the custody of the authorities on suspicion of being intended for the Confederates. Perhaps no vessels have ever attained a reputation more disproportionate to their real powers of offense and defense than these two ships; for, although thinly armored and but weakly armed, they have been frequently described as most formidable vessels. We do not, however, propose to discuss the merits or demerits of those ships, but simply to add respecting them that, although intended to keep the sea, and therefore provided with a moderate amount of sail, they have proved very inferior sea-boats, the Wivern having particularly distinguished herself by excessive rolling. The advocates of the turret system have always argued that the bad performance of these ships was in a great measure the result of their moderate size (they being of less than 1,900 tons burden), and have urged the desirability of bringing the turret system into competition with the broadside system in ships which, in point of size, could compare with our armored frigates; this trial will be rendered possible very shortly, when the Captain and Monarch are complete for sea. It would, of course, be folly to predict exactly what results will be obtained; one thing, however, seems certain, viz: that, as sea-boats, both of these vessels will prove far superior to any existing turret-ships; and there is every probability that the Monarch, if not the Captain also, will prove as efficient under sail as our broadside iron-clads.

Although classed together as sea-going turret-ships, there are some very great differences between the Captain and the Monarch. The former, we need hardly say, is supposed to be the fullest expression of Captain Coles' ideas respecting ships of the class; the latter was designed in the Controller's Department at the Admiralty, and must, therefore, be regarded as the representative ship of the type of which the naval officers, then at the head of our navy, most approved, and which the professional officers did their best to perfect. Looked at by an unprofessional spectator, the Monarch presents no special feature; she has the lofty sides and upper deck of a broadside ship, and is rigged in the usual manner. In fact, in all respects except the turrets, and some special arrangements of flying or hurricane deck for carrying boats, consequent upon the turret armament, the Monarch closely resembles the broadside ships which immediately preceded her. What would be the central battery on the main deck—if she were a broadside ship—is the space in which the turret-beds are built; and there are, of course, no port-holes in the side armor. On this central space or battery the armor rises to the height of the upper deck, about 14 ft. above the water; before and abaft it there is an armor belt, extending throughout the length, and reaching from about 5 ft. below the water-line up to a nearly equal distance above it. Instead of this, the Captain has her upper deck only 8 ft. above water, and throughout the length the armor reaches from a few inches below this deck down to about 5 ft. below water. She has a poop and forecastle above the upper deck, and a flying deck extends along the length between, this light deck being comparatively narrow, and being intended, unlike that of the Monarch, for working the sails. The Captain has tripod masts. Her turrets pass down through the upper deck, and the beds are built upon the deck below; the guns are, therefore, only about 9 or 10 ft. above water, while in the Monarch they are 15 or 16 feet. This is, doubtless an advantage of considerable importance in a ship like the Monarch, intended to fight in a seaway, since she could use her turret-guns when the Captain would be powerless; but this advantage has been purchased at a considerable cost. First of all, the Monarch is 800 tons burden more than the Captain, although she only carries about the same weight of turrets and guns as the Captain, and has armor of the same thickness; the different disposition of the armor in the Monarch requiring a much greater weight of armor than the Captain's system would require, and the lofty sides, of course, adding to the weight of hull. Then the Monarch, being a larger ship, has a greater weight of equipment, heavier and more powerful engines, and a greater weight of coal than the Captain, all of which, of course, must be regarded as the result of the difference of types. The side armor of the ships is nearly all 7-in.; the Captain has a little 8-in. in wake of the turrets. On the turrets the armor is 8-in. and 10-in., the greater thickness being used near the ports. The turrets, of which there are two in each ship, will each carry two 25-ton guns, throwing 600-lbs. shot. Besides these the Monarch has three $6\frac{1}{2}$-ton guns, two of which are in an armored bow-battery, and the third in an armored stern-battery; the Captain has two $6\frac{1}{2}$-ton guns, carried unprotected on the poop and forecastle.

In conclusion, we would remark that the turret system is at a great disadvantage when applied in a full-rigged sea-going ship like the Monarch or the Captain. By means of poops, forecastles, stays, shrouds, tripods, or other obstructions, it becomes impossible to fire the turret guns in very many directions, and hence the chief merit of the turret system—an all-round or nearly all-round fire—is forfeited. Direct fire, either ahead or astern, both of which are most important, is entirely out of the power of the turret guns of both ships; the Monarch, by means of the bow and stern batteries, making up for this failure to some extent, while the Captain is the most unsatisfactory of our recent ships, in so far as what are termed "arcs of impunity" are concerned. In fact, no greater contrast between ships can exist than that between the Captain, which has no power of firing within, say, 15° of the line of keel either ahead or astern, from her turrets, and the broadside ships of the Invincible class, which, from armored batteries amidships, can command an all-round fire. In this most important respect the broadside-ships have completely outstripped the turret-ships.

CHURCH'S EQUILIBRIUM SLIDE VALVE.

From "Engineering."

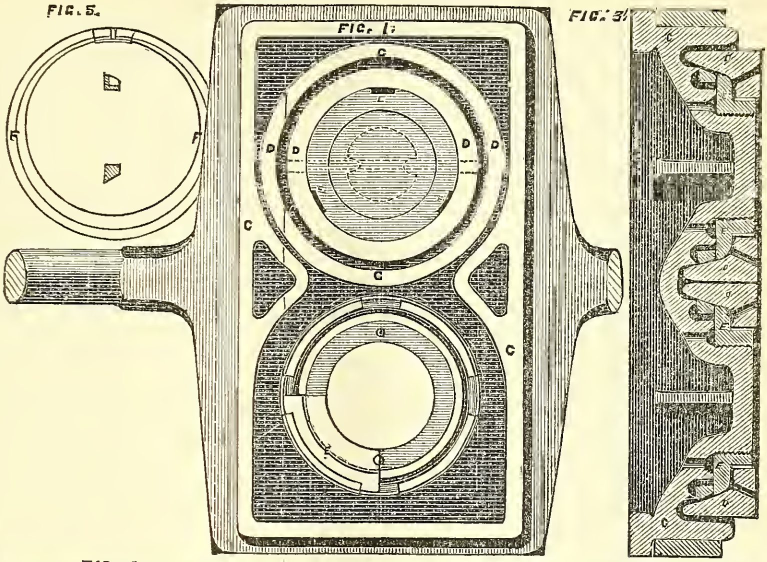

FIG. 2.

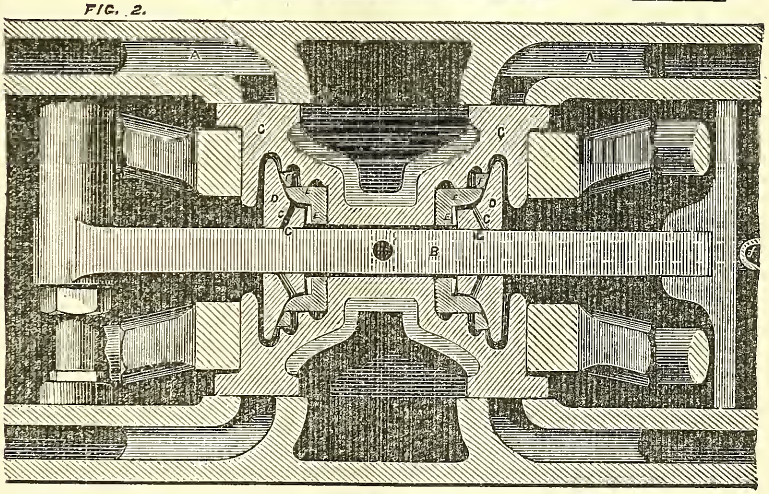

Fig. 4.

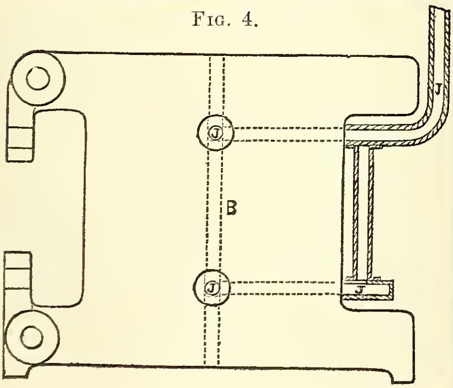

In the course of our account of the Conversazione recently held at the Institution of Civil Engineers, we mentioned a pair of equilibrium slide-valves, designed by Mr. W. C. Church, and which were exhibited on that occasion. In fulfillment of a promise then made, we now publish engravings of Mr. Church's arrangement, which will explain it fully. The particular pair of valves shown, on the occasion above referred to, had been taken for exhibition from a locomotive on the Great Northern Railway, on which line they had run up to the time of their removal 740 miles; and this trial, although not a long one, gave very promising results. The valves have, we believe, since been replaced in the engine to which they belong, in order that they may undergo a more extensive trial, and that the saving of fuel, which is obtained by their use, may be accurately ascertained; and we hope in due time to lay the full particulars of this trial before our readers. In the meantime we may remark that Mr. Church's equilibrium slide-valves, although at first sight apparently rather complicated, are in reality of simple construction. There are but few parts about them, and the pieces are all of such forms that they can be finished in a lathe, scarcely any hand labor being required to fit them together. The whole of the details, moreover, bear evidence of having been carefully considered, as the description of the arrangements which we shall now proceed to give will show.

Referring to our engravings, fig. 1 is a back elevation of one of the slide-valves we have mentioned, this valve being constructed for two caps or rings, D D, of which the object will be explained presently. In the figure one cap is shown in its proper position, and the other removed, showing a quarter of the junk ring. Fig. 2 is a vertical section through the steam chest, and fig. 3 is a section at right angles to fig. 2. Fig. 4 represents, detached, the division plate, with the pipes for carrying off any leakage of steam between the backs of the valves and the insides of the caps. Fig. 5 represents the metallic packing-ring detached. In these figures, A A are the steam-ports, B the division-plate, C C the slide-valves, D D the caps or rings applied to the back of the slide-valves, E E the junk rings, F F the metallic packing rings for keeping the caps, D D, steam tight.

In considering the action of Mr. Church's valves, it must be understood that the object of the caps is to prevent the steam in the steam-chest from acting on those parts of the back of the valve which are enclosed within the caps, or, more strictly speaking, those areas which are represented as enclosed by the lines of contact between the caps, D D, and the metallic packing rings, F F. It will be seen from the section of the cap (figs. 2 and 3), that the latter is of a conical form, both internally and externally, the object of this form, internally, being to enable the metallic packing ring, F, to act as an expanding ring, in order to press the cap up to the division-plate, B, when the steam is shut off from the steam-chest. The circular grove, G, and the holes, G^1, in each cap, D, and the holes, E^1, in the junk ring, E (seen best in fig. 1), are intended to carry off all steam that may leak between the surface of the cap, D, and the division-plate, B (or second valve, as the case may be), at a part of the cap that will prevent the occurrence of a pressure to remove the cap, D, from off its bearing face.

It will be seen that when the steam is in the steam-chest, the cap, D, is pressed up against its bearing face by the steam acting on an annular area, the width of which is equal to the difference in diameter between the metallic packing ring, F, and the cap, D. The caps, D D, are free to move on a fixed center, at a point, H, so as to compensate for unequal wear of the valves or the cap face, or for one side of the valve to lift in case of the engine priming. This is a feature in Mr. Church's arrangement which is worthy of special notice. The metallic packing ring, F, is also arranged in such a manner as to be capable of accommodating itself to the varying position either of the cap or valve. The said ring is so arranged that the steam presses it both outwards against the cap, D, and upwards against the junk ring, E.

The metallic packing ring, F, is also made conical on its outer circumference, for two reasons: first, in order to reduce the area of superficial contact between itself and the cap, D, and, secondly, in order to give the steam a larger area to act upon at the bottom of the ring; so that no amount of leakage on the top of the latter shall be able to place it in equilibrium, and thus destroy its required action. The holes, passages, and pipes, J and J^1, in connection with the division-plate, B, are intended for carrying off any steam that may accumulate in the cap, D. The pipes, J^1, are in communication with the atmosphere, and are furnished with cocks, so that in the event of any accident occurring to the caps, D D, these cocks can be closed; the effect of which will be merely to alter the action or condition of working of the valves, and reduce them to valves of the old construction, a great practical convenience.

The division-plate, B, is adjusted in position as required at the back end of the steam-chest, by means of set screws, as shown in fig. 2, and at the front end by means of two brackets fixed to the steam-chest lid, so that when the steam-chest lid is removed, the valves can be withdrawn in the usual way without disturbing the division-plate. Another mode of fixing the division-plate is to slide it into a groove provided for it in the top and bottom of the steam-chest. We should also mention that in one arrangement of his valves, Mr. Church employs no division-plate at all, but lets one valve work on the back of the other, and he at the same time arranges the steam ports so that the passages leading to the cylinders are much shortened. The adoption of this plan, which possesses several good points, of which we may speak more fully on another occasion, of course renders special cylinders necessary.

Mr. Church gives the following rule as that which he employs to determine the area of the cap or caps to be applied to the back of the valves.

"That portion of a slide-valve which does not leave the face of the ports at the end of the stroke, less the area of the steam ports, represents the area on the back of the valve, upon which there is a constant pressure, varying only with the pressure of steam in the boiler. And as it is the object of these improvements to remove this pressure, it becomes desirable to point out the following rule for determining the area of the back of any slide-valve, from which the said pressure may be removed, by the application of a cap or caps, as hereinbefore described. Let A equal the area of that part of the valve that leaves the face at the end of the stroke; C the total area of the steam ports; D the area of the annular cap or caps, for removing the pressure from the back of the valve. Then the formula will stand as follows:

$$A - (B + C) = D.$$

"To take an example—Let a slide-valve be supposed measuring $11\frac{1}{4}$ in. by 19 in. The total area of the back of this valve would be equal to 213.75 sq. in. The area of that part of the valve which leaves the port faces at the end of the stroke may be taken in this case as equal to 43.75 sq. in. The total area of the two steam ports is equal to 49.50 sq. in. Then 213.75—(43.-75 + 49.50) = 120.50 sq. in.; which shows the area of the cap or caps to be applied to the backs of the valves, or, more strictly, the area to be contained within the circle described by the line of contact between the cap or caps and the elastic metallic packing ring."

WHO INVENTED THE STEAMBOAT?

From the "American Artisan."

The question of who invented the steamboat could be correctly answered only by enumerating several projectors whose efforts succeeded each other during a period of three-fourths of a century. The propulsion of boats by paddle-wheels is said, indeed, to date back to the time of the Romans, but precisely in what way they applied the power is not known. As long ago as 1682, Prince Rupert, the courtly mechanician of the heyday of the Stuarts, propelled his barge in this way. In 1726, one Dr. Allen printed a pamphlet in London, in which he proposed to urge a vessel forward by a jet of air or water ejected from a pipe at the stern. He thought that by using steam power he could make three miles an hour in this way. In 1737, Jonathan Hulls published his invention, which may be considered the archetype of the modern steamboat. It had a paddle-wheel arranged at the stern, and worked by a steam-engine; but instead of the crank, the application of which to the steam-engine had not then been invented, Hulls employed a complicated set of devices for giving motion to the wheel. After this there was little or nothing suggested in the line of steam propulsion until 1782, when the Marquis de Jeoffroy tried a steamer on the river Loire in France. Instead of a paddle-wheel, he had the paddles arranged upon an endless belt that traversed two supporting pulleys, but the apparatus was not successful. Two years later, James Rumsey commenced experiments with a boat 80 ft. long, in which an engine worked a vertical pump that drew in water at the bow and ejected it at the stern. The reaction of the effluent water moved the vessel along at the rate of four miles an hour. This seems to have been a revival in some sort of Allen's plan; and substantially the same system has been frequently re-invented since, a recent and notable example of these jet-propellers being found in the English vessel, the Water Witch. In 1786, John Fitch made public his project of moving vessels against wind and tide by fitting them with vibratory paddles worked by steam-power. There were twelve paddles, six on each side of the boat, one-half of these on either side working alternately with the other half of the number. The paddles were designed to have a stroke of $5\frac{1}{2}$ ft., but it does not appear that the plan was ever subjected to actual trial. Fitch, however, did not rest content with this plan, else he would never have been heard of afterward, but was also the inventor of the screw-propeller, and also of the combination in one vessel of the screw and side-wheels—the principle of propulsion adopted in the Great Eastern. This screw-propeller, and mode of using it in connection with paddle-wheels, was shown by experiment, in 1796 or 1797, on the collect Pond, a sheet of water that in those days rippled where the grim Egyptian pile, the New York City "Tombs," now stands. The vessel is described as a common long-boat, 18 ft. long and 6 ft. wide, and steered at the bow. The steam-boiler was constituted by a twelve-gallon iron pot, with a lid made of a piece of plank firmly fastened down. The engine had two wooden cylinders, and the mechanical appliances for working the screw and paddle-wheels, although rude, were arranged with such effect that a speed of six miles an hour is said to have been obtained. The inventor, however, was too poor to continue his experiments, and too impatient of argument and contradiction to interest incredulous moneyed men of the day in his enterprise. The boat, with a part of its machinery, was drawn up and left on the shore of the pond, and piece by piece this type of the future steam-vessel fell to decay, and the children of the neighborhood gathered up its fragments and carried them home for kindling-wood. A few years later, Fitch, a broken and embittered old man, with feeble health and ruined fortunes, poisoned himself with opium, and was buried in Bardstown, Ky. To this day no monument or head-stone marks his resting-place, but the fulfillment of his prophecies is shown wherever the steam-whistle sounds over the placid waters of rivers or the turbulent foaming of the sea.

While Fitch and Rumsey were thus experimenting with steam propulsion, others were making trials in the same direction, with more or less success. As an illustration of the blunders that even truly great men will sometimes make, it may be noted that about the year 1786, Dr. Franklin proposed to propel vessels by the direct action of steam upon the water, which was, of course, found to be utterly out of the question. About the same time, Oliver Evans advocated the employment of paddle-wheels, and a boat was run for a short time between Philadelphia and Bordentown, but no details of its means of propulsion have been handed down. In 1787, Mr. Patrick Miller, of Dalswinton, in Scotland, made a double vessel, moved by a paddle-wheel at the stern, and two years after constructed another, 60 ft. long, that went at the rate of seven miles an hour, but proved too weak to bear the action of the machinery. It is said that these experiments cost Miller upwards of $150,000, for which he received no return whatever. A dozen years afterwards, William Symington, who had made the steam-engines for Miller's boats, induced Lord Dundas to build a steam-vessel for towing craft on the Forth and Clyde canal. This, the Charlotte Dundas, dragged along two sloops of 70 tons burden each against a strong head wind at a speed of 3½ miles an hour. The owners of the canal, however, refused to use this means of towing, because of the liability of injuring the banks by the undulations of the water—the principal reason to this day why steam has not been applied in canal propulsion. From this time forward steam navigation began to assume a more promising aspect and more tangible shape. In 1804, John Stevens, of Hoboken, N. J., had a boat 24 ft. long, fitted with a paddle-wheel at the stern, which, for short distances, made eight miles an hour. The greatest benefit, however, conferred by Stevens upon the engineering world was in the invention of the tubular boiler—a principle of construction that has worked wonders in steam-generators for all purposes.

We now come to the efforts of Robert Fulton, a man who possessed business talent, and the faculty of mastering the details of whatever he undertook, in a no less degree than inventive skill. He left Philadelphia in 1786, and went to London, where, as early as 1793, he communicated with Earl Stanhope concerning steamboats—this nobleman being something of an enthusiast on the subject, and having a plan of his own, which has come to be known as that of the duck's-foot propeller. This was simply a kind of folding oar, which opened to act against the water when pushed outward, and closed when drawn back at the end of the stroke. After this Fulton went to France, where he brought before Napoleon a method for blowing up the English ships; but although he made an apparatus by which he was enabled to remain under water for a period of 4½ hours, he did not destroy a single vessel of the enemy. His journey to France, however, did him some good, for it was there that he became acquainted with Chancellor Livingston, who furnished the funds by which he was finally enabled to put his plans for steam propulsion into practice. Assisted by Livingston, he, in 1803, made experiments on the river Seine with a paddle-wheel boat 60 ft. long. The results were so favorable that it was concluded to attempt, without delay, the introduction of steam navigation on American waters. An engine was ordered from the English workshops of Boulton & Watt, and was duly forwarded to New York. In 1807, the Clermont was launched on the East River, and at once commenced running on the Hudson, between New York and Albany. Since then, until the present hour, there has not been a single day when vessels have not been propelled against wind and tide by the power of steam—the Clermont having been, if not the earliest practical steamboat, at least the first steam-vessel to establish a system of regular trips between different places.

METROPOLITAN RAILWAY ROLLING STOCK.

From "Engineering."

A few weeks ago there appeared in a contemporary* an article on the rolling stock now in use on the Metropolitan Railway, this article containing what was professedly a comparison of the stock belonging to the Metropolitan Railway Company proper with that employed by other companies running trains over the Metropolitan line. The deductions drawn from this comparison were so startling, and in some respects so at variance with our own ideas on the subject, that we determined to investigate the matter further, and the result has been that we have, as we anticipated, discovered in our contemporary's article many grave mis-statements of facts which, in common fairness to those by whom the Metropolitan rolling stock was designed, deserve to be exposed. And here we may remark that although, in the instance we have referred to, we consider that the rolling stock of the Metropolitan line has been most unjustly criticized, yet we are by no means desirous of having it supposed that we consider the stock, as a whole, perfection. With the engines we consider that little or no fault can justly be found. They are in all respects thoroughly well adapted to the exceptional work they have to perform; their construction is such that their working expenses are very moderate; and, as we shall show presently, their weight is in no way excessive when all the circumstances of the case are taken into consideration.

With the carriages the case is somewhat different. Their weight (16 tons each empty) is no doubt too great even when the excellent accommodation they afford is taken into consideration; but in speaking of this weight it must be remembered that it was incurred under exceptionable circumstances. Before the Metropolitan line was opened were many who affirmed—and apparently with a certain amount of reason—that it would never be a success. It was asserted that the public would never "take" to an underground line; that they would object to travel to and fro, shut out from the light of day; that it would be found impossible to keep the tunnel properly ventilated, and that, in fact, the whole affair was a mistake. How, as a matter of fact, the public *have* "taken" to the line and used it as no line was ever used before, is well known; but it is not known, and never can be known, to how great an extent this has been due to the excellence of the accommodation which Mr. Fowler's judgment led him to provide. In station appointments and passenger accommodation generally the Metropolitan line set an example to the whole of the railways in the kingdom; and the example has, we are glad to say, been appreciated and followed. At the time the Metropolitan line was opened, the carriages employed by all our leading railway companies for metropolitan or local traffic were practically identical with those used on trains running long distances. Yet in the former case, where people are continually entering and leaving the carriages, there is a greater necessity for ample height and space between the seats, and Mr. Fowler, therefore, had constructed for the Metropolitan line—where the stoppages occurred at exceedingly short intervals—carriages with far greater head-room, and, indeed, more spacious generally than any running at that date. It was on the Metropolitan Railway, also, that the public were first indulged with the luxury of thoroughly well-lighted carriages; and it was in fact on this line that the problem of lighting railway carriages by gas was first successfully worked out on anything like an extensive scale. Of course the extra accommodation and the addition of the gas-holders, etc., all involved additional weight

* See V. N.'s Magazine, July page 589.

in the rolling stock; and it is, we think, not to be wondered at that in first designing carriages involving many novel points of construction, this additional weight should have been allowed to become somewhat greater than it need have been.

Leaving generalities however, let us state briefly the accusations against Mr. Fowler's rolling stock contained in the article to which we have referred. As regards the engines, it is affirmed that the driving wheels (the diameter of which is wrongly stated as 5 ft. 6 in. instead of 5 ft. 9 in.) are inexcusably large, and that these large wheels led to the adoption, as a necessity, of large cylinders; our contemporary adding: "We need not stop to explain how great an augmentation of weight this entailed." Further, it is stated that, "It was next assumed that the curves would be bad to get round with a six-wheeled engine, therefore a bogie was introduced principally because the engine was made too long to begin with. This further increased the weight, and so, finally, Mr. Fowler produced the now well-known narrow gauge standard Metropolitan engine, weighing nominally 42 tons, but in all probability at least 45 tons loaded. This monstrous machine is employed to haul trains consisting of five not less monstrous carriages . . . The driving wheels are much too large, the machine too long, and, above and beyond all, the enormous weight of the machine constitutes a grievous defect." Our contemporary then goes on to say that although it has apparently brought grave accusations against Mr. Fowler, yet that these accusations have been made much more forcibly by "no fewer than three of the largest and most powerful railway companies in the kingdom," these being stated to be the Great Northern, the Midland, and the Great Western companies. Moreover, a detailed comparison is made between the Metropolitan and Great Western rolling stock; but this comparison we shall leave for the present, and shall in the first place consider the statements concerning the Metropolitan engines, which we have reprinted above.

To begin with, then, let us consider the assertion—urged so strongly by our contemporary—that the wheels of Mr. Fowler's engines are "much too large." Now of course we cannot say precisely what particular dimension "much" may denote, but judging from the praise bestowed (and much of it most deservedly) on the new Great Western engines, we are inclined to believe that, in this particular instance, the term stands for 9 in., the driving wheels of the new Great Western engines being 5 ft., and those of the Metropolitan engines 5 ft. 9 in. in diameter. It would be foreign to the purpose of the present article to enter into all the arguments that have been advanced for and against large driving wheels, and we shall therefore merely refer to the two principal ones, these being, first, that the larger the driving wheels the less will of course be the number of revolutions made in running a given distance, and the greater, therefore, will be the durability of the tyres and of the wearing surfaces of the "motion" generally; and, secondly, on the other hand, that the larger the driving wheels the greater will be their weight, and the greater also will be the size and weight of the cylinders, pistons, and their connexions, requisite for giving a certain tractive power. Our contemporary, whose remarks we are criticizing, has stated that the "much" too large wheels and cylinders of Mr. Fowler's engines have led to a "great augmentation of weight," but it has deemed it unnecessary to explain how this "great augmentation" is caused. As a fact, the two pairs of coupled wheels of the Metropolitan engines if decreased from 5 ft. 9 in. to 5 ft. in diameter, would be reduced in weight but about 13 cwt.; while the corresponding reduction which might at the same time be made in the size of the cylinders (the tractive power of the engine being maintained the same as at present) would amount to about $1\frac{1}{2}$ cwt., making the "great" total of $14\frac{1}{2}$ cwt. as the saving under these two heads. Of course with the smaller cylinders some reduction might be made in the weight of the pistons, piston rods, connecting and coupling rods, etc.; but this would not amount to much if the bearing surfaces were maintained of such dimensions as to give the same durability as is obtained with the larger wheels. The question then arises whether these little savings in weight would compensate for the more rapid wear of tyres, etc., due to the reduced size of driving wheel; and the only way in which we can answer this question is by referring to the proportions which the locomotive practice of the last few years has shown to be best suited for engines working traffic similar to that on the Metropolitan Railway. In the first place we find that Mr. William Adams, of the North London Line (an engineer who has probably had more experience in working what may be called "omnibus" traffic than any locomotive superintendent in the kingdom), although he has lately built some engines with 5 ft. 3 in. coupled wheels, has for many years past employed, as his standard locomotives, engines having coupled wheels and cylinders of precisely the same dimensions as Mr. Fowler's; while the Great Northern, the Great Eastern, the London, Chatham, and Dover, and the South-Eastern lines are employing locomotives with 5 ft. 6 in. coupled wheels for their local traffc. A reference to the best practice therefore shows that as regards the size of their driving wheels, there is nothing unusual in the Metropolitan engines, and that there is no foundation for the assertion of our contemporary that these engines have wheels "much too large;" while, moreover, the Midland Company (who are expressly cited by our contemporary in support of its arguments) are running their "metropolitan" trains with engines having driving wheels no less than 6 ft. 2 in. in diameter.

Next, it is stated in our contemporary, that the Metropolitan engines were made too long, and that it was then endeavoured to compensate for this by fitting them with a bogie. If the writer of the article in question had ever designed a locomotive, he would probably never have made so silly an assertion. The fact was, that Mr. Fowler considered—and with good reason—that a locomotive with a flexible wheel-base was best suited for working a line with numerous curves like the Metropolitan, and he, therefore, adopted bogie engines, the result, of course, being that the total wheel-base was rendered longer than it otherwise would have been. In this adoption of a long and flexible wheel-base, Mr. Fowler is also supported by the practice on most of our principal lines, as the following Table, giving the wheel-bases, etc., of engines employed in working metropolitan traffic, will show:

Name of line to which engines belong.	Total wheel-base.	Length of rigid wheel-base.	Arrangement adopted for giving flexibility.
North London	22 2	8 0	W. Adams' bogie.
" "	20 8	8 0	" "
Great Northern	19 3	7 6	W. B. Adams' radial axle-boxes.
South-Eastern	20 6	7 3	W. Adams' bogie.
Metropolitan	20 9	8 10	Bissell's bogie.

The new "Metropolitan" engines of the Great Western Company and those of the Midland Company have certainly rigid wheel bases, the former being 15 ft. 3 in., and the latter no less than 16 ft. 6 in.; but we have yet to learn how the flange wear of the tyres of these locomotives will compare with that of the bogie engines used by other companies; while we must remember that increased flange wear means also increased wear and tear of the permanent way. As for the increased weight due to the adoption of the four-wheeled Bissell bogie on the Metropolitan engines, it probably amounts, we believe, to about 3 tons 2 cwt.; but in return for this there is obtained not only the decreased wear of flanges and rails, but also increased safety. And here we may remark that the statement made by our contemporary, that on the Metropolitan Railway "the bad curves are few in number, and at the worst can do no great harm, because the speed at which they are traversed, as at King's-cross, for example, is low," is far from expressing the state of affairs correctly. All who have ridden over the Metropolitan Railway on an engine well know, or should know, that the line is essentially one with frequent curves; and, although none of these may be considered exceptionably sharp, according to the light in which such matters are now viewed, yet numbers of them are of but 10 chains radius, and are traversed at speeds of over 25 miles per hour.

We now come to the third principal objection made by our contemporary to Mr. Fowler's engines, namely, to their alleged "enormous weight," which it said exercises a most destructive action on the permanent way. Says our contemporary: "There is no denying the fact that the standard engines play havoc even with the permanent way of the Metropolitan Railway, smashing off the tables of steel rails, and grinding out the best Bessemer track, perhaps in the world, as though it were made of iron." Now, notwithstanding the assertions of our contemporary we most emphatically deny that the steel rails on the Metropolitan railway are being crushed or having their tables smashed off by the loads imposed upon them. We lately walked over a considerable length of the line and found no signs whatever of anything but fair and even wear taking place, except at stations where a certain amount of lamination of the rails is caused by the action of the brakes and by the occasional slipping of the engines when starting. There are now in the Metropolitan line, between King's-cross and Farringdon-street, Bessemer steel rails which were laid down in April and May, 1866, and which have consequently been on the road upwards of three years. During that time they have been traversed by the following numbers of trains:

Metropolitan	161,000
Great Western	39,000
London, Chatham, and Dover	10,000
Great Northern	17,000
	227,000

Even this vast number does not include empty engines passing to and from sheds, and which during the time we have mentioned would probably amount to not less than 15,000 or 20,000. Notwithstanding that they have carried this enormous traffic, the rails show nothing but an exceedingly slight and perfectly uniform wear, and there are no signs whatever of "smashing" due to excessive loads. At the stations the skidded carriage wheels do undoubtedly produce lamination, and it is curious on passing the finger—or still better, the point of a pin or penknife—over the rails to feel how the surface has, as it were, been rubbed down in the direction of the traffic. This, however, has nothing to do with the weight of the engines. Of this weight we shall have more to say when considering the comparison between the Metropolitan and Great Western locomotives; and in the meantime we shall merely remark that the correct weight in working order is 42 tons 3 cwt.—not "at least 45 tons," as stated by our contemporary; while the weight resting on the coupled wheels is 30 tons. These weights are practically the same as those of the standard engines used by Mr. William Adams on the North London line, while the Midland "metropolitan" locomotives, which are stated by our contemporary to be "a modification of Mr. Fowler's design, the engines weighing much less, however," are, in reality, engines with a rigid wheel-base of 15 ft. 6 in., having 16½ in. cylinders, with 22 in. stroke, 6 ft. 2 in. coupled wheels, and weighing, in working order, 43 tons 4 cwt., of which over 32 tons rest upon the coupled wheels.

We shall now consider the comparison made by our contemporary between the standard Metropolitan locomotives and those recently placed on the line by the Great Western Company for working their metropolitan traffic; and in the first place it may be as well that we should give a few particulars of the latter engines, and the work done by them. The new Great Western locomotives, then, have inside cylinders 16 in. in diameter, with 24 in. stroke, and they are carried on six wheels, the driving and trailing wheels, which are 5 ft. in diameter, being coupled, and there being a single pair of leading wheels in front. The wheel base is 15 ft. 3 in., and their weight in working order is a little over 33 tons, of which about 23 tons rest on the coupled wheels. And here, before proceeding further, we may remark that in carrying out our comparison between the Metropolitan and Great Western engines, we are very far from wishing to find fault with the latter. They are of thoroughly good and remarkably neat design, and we believe them to be well adapted for the work which they have to perform; but this work is not the same as that which is required of the Metropolitan engines, and it is in neglecting to note this fact that our contemporary has so greatly erred. The regular load drawn by the Great Western engines over the Metropolitan line between Bishop's-road and Moorgate-street, consists usually of six or sometimes seven carriages, two of these carriages carrying each 40 passengers, including the guard and brakesman, and the remaining carriages accommodating each 32 passengers. The six-carriage trains have thus seat room for 202, and the seven-carriage trains for 240 passengers. Regarding the weight of these carriages we have no precise information; but they are of light construction, and we should think that they probably weigh about 6½ tons each, or about .2 ton per passenger carried. Of the total distance run by the Great Western engines, about five-ninths is run on the Metropolitan line, and the remainder on the Great Western line, where no condensation of the exhaust steam is required. This fact should be taken into consideration in comparing the Great Western and Metropolitan locomotives. The usual load drawn by the latter engines, we should state, consists of a train of five carriages, accommodating 352 passengers, this train being made up as follows: One first class, holding 48 passengers; one composite, carrying 24 first class and 40 second class passengers; one second class, holding 80 passengers; and two third class, accommodating together 160 people. The carriages weigh 16 tons each, their weight being thus .312 ton per passenger for the first class; .25 ton per passenger for the composites; and .2 ton per passenger for the third class.

Arguing on these premises, our contemporary says: "We have, then, the Great Western Company doing the same work that the Metropolitan are doing, with a dead weight less by at least twenty-five tons per train, if we assume ten of the Great Western carriages, to carry only as many as five of the Metropolitan carriages." Now, as a fact, the ten Great Western carriages could not carry so many passengers as the five carriages forming the usual Metropolitan train, while the saving of weight would, we firmly believe, be under twenty-five tons rather than over it. The assertion that the Great Western Company are doing the same work as the Metropolitan Company with lighter engines and much less dead weight, we must decidedly deny. The maximum train worked by the Great Western Company over the Metropolitan line consists, as we have said, of seven carriages, and taking this as the standard of comparison with the Metropolitan five-carriage train, we find the relative dead weights to be as follows:

	Metropolitan.	G. W. R.
Weight of engine......	42 tons.	33 tons.
" train, about	80 "	about $45\frac{1}{2}$ "
Total of engine and train, about	122 "	about $78\frac{1}{2}$ "
Number of passengers carried............	352	240
Weight of engine per passenger	.119 ton	.137 ton
Weight of engine and per passenger about.	.346 ton about	.327 ton

We thus see that the weight of the engine per passenger drawn is actually less in the case of the Metropolitan than in the Great Western trains, while the total dead weight per passenger is nearly the same in the two cases. It may be said, and no doubt truly, that the Great Western engines are underwork; but the same is equally true of the Metropolitan locomotives; and, in fact, the latter have been designed for working not merely the present traffic, but the traffic which it is expected will be obtained when the whole line is completed. In fact, the short stations on the line are now being lengthened, to allow of longer trains being worked. Moreover, in comparing the performance of the two sets of engines, it must be borne in mind that while the Great Western trains traverse but $4\frac{1}{2}$ miles of underground line, the Metropolitan trains are worked from Moorgate-street to Westminster, a distance of $9\frac{1}{2}$ miles, and the Metropolitan engines thus require and carry 1,000 gallons of water for condensing purposes against 750 gallons carried by the Great Western engines. The maximum gradient also on that portion of the line traversed by the Great Western trains is 1 in 100, whereas between Praed-street and Westminster there are several gradients of 1 in 70. Thus, the work done by the Metropolitan is much heavier than that performed by the Great Western locomotives.

Taking all things into consideration, we cannot consider that the Metropolitan engines are too heavy for the duty demanded of them. They are certainly 9 tons (not 12 tons, as stated by our contemporary) heavier than the Great Western engines, but they have the advantage of a greater firegrate area, a greater firebox heating surface, a greater water capacity in the boiler (an important matter for engines working underground traffic) a greater adhesion weight, a greater tank capacity, and last, but not least, they have a flexible wheel-base, and are fitted with a compensating beam between the coupled wheels. As regards tractive power, the two sets of engines are practically identical, the tractive force exerted for each pound of effective pressure per square inch on the pistons being 100.5 lbs. in the case of the Metropolitan, and 102.4 lbs. in that of the Great Western locomotives. They would thus possess, as far as cylinder power is concerned, equal capabilities for starting a train; but on an underground line, where the exhaust cannot be discharged into the chimney, the additional firebox capacity and water space in the boiler would give the Metropolitan engines an undoubted advantage for maintaining speed.

Our article has already extended to a greater length than we intended, but we cannot conclude it without directing attention to a most extraordinary conclusion arrived at by our contemporary with regard to the facts we have been considering. It says: "If Mr. Fowler's method of working Metropolitan traffic can be made to pay—and it is—then much more should the Great Western system pay. *In the case of the engines alone, the cost of transmitting each ton of dead weight from place to place cannot be much less than 2d. per ton per mile.* Taking the very moderate estimate of 20,000 miles as the distance run each year by each engine, we have a saving of 12 tons less in the Great Western engines, as compared with the standard Metropolitan engines, of £166 per engine per annum, or for the Metropolitan Railway Company, with 36 engines, a saving of, in round numbers, £6,000 per annum!" The italics are our own, and we fancy that the passage we have italicized will astonish most railway men. As a fact, the locomotive and carriages expenses on the Metropolitan line average about 13d. per train per mile, and taking the mean gross weight of the trains as low as 130 tons, we find the mean cost of transport per ton per mile to be but .1d. instead of 2d. as stated by our contemporary. Extraordinary, however, as is our contemporary's statement that the cost of transport is not less than 2d. per ton per mile, the arithmetic by which this cost is made to show a saving of £166 per engine per annum is still more extraordinary. According to ordinary methods of calculation 12 tons carried 20,000 miles at 2d. per ton per mile would give £2,000 not £166! The real difference of weight of the engines, however, is 9 tons not 12 tons, and at .1d. per ton per mile this gives for 20,000 miles per annum, £75 per engine per annum, or £2,700 for the 36 engines, a sum which we think would be *hardly* compensated for by the decreased efficiency.

IRON AND STEEL NOTES.

Smelting, Carburizing, and Purifying Iron.—Mr. Isham Baggs, of High Holborn, has patented some processes by means of which the smelting, carburization, and purification of iron are greatly facilitated. In charging the furnace, the coal or coke usually thought necessary for smelting is in a great measure dispensed with, and in its place, Mr. Baggs burns in the smelting furnace coal gas, hydrogen, carbonic oxide, or other combustible gas or gases, and also the vapor of petroleum, naphtha, and other hydrocarbons under pressure and in combination with a blast of hot or cold air. In the case of the inflammable hydrocarbon vapors, the same may be forced into the furnace under the pressure of their own atmospheres, or by means of mechanical appliances. The gases and vapors which are employed for the purposes of this invention may be previously mixed with the air furnished by the blast, or may be caused to meet the air in the furnace or at the tuyeres. The proportions of the mixture when a combination of gas or vapor and air is employed are subject to constant regulation by valves. One very convenient mode of obtaining combustible gases for the purposes of this invention is to generate coal gas in the usual way, and then carbonic oxide, and to blow air or carbonic oxide gas under pressure through the retort containing the residual coke.

For the purpose of carburizing the iron, whether in or out of the furnace, as may be desirable, coal gas or other carbides, or other materials containing carbon, are blown through the furnace or brought into contact with the molten metal by blowing them through it. Carbon in any suitable form or combination may also be directly introduced into the furnace for the purpose of carburization, and although generally for smelting purposes it is desirable to exclude all solid mineral fuel from the furnace as part of the charge, yet where a suspension of operations is necessary, such a charge of coal, coke, or other fuel may be introduced into the furnace as will prevent the materials on renewal of work from falling through the crucible or any iron remaining therein or below it from being permanently solidified. When purification is required, hydrofluoric acid is blown through the molten metal on its way from the furnaces, the gases being mixed with common air or with some gaseous diluent.—*Mechanics' Magazine.*

Iron and Steel Institute.—On Wednesday evening, June 23d, at the rooms of the Society of Arts, the first meeting of the newly formed Iron and Steel Institute, which was very fully attended by ironmasters from the North, Lancashire, South Staffordshire, South Wales, Middlesborough, etc., was held under the presidency of his Grace the Duke of Devonshire, the President, who delivered a lengthy and exhaustive inaugural address. His Grace explained the objects of the institute, which are to afford a means of communication between members of the iron and steel trades upon matters bearing upon the respective manufactures, excluding all questions connected with wages and trade regulations, and to arrange periodical meetings for the purpose of discussing practical and scientific subjects bearing upon the manufacture and working of iron and steel. He reviewed the success which had attended the formation of scientific and agricultural societies, and saw no reason why equal advantages should not accrue to the iron trade by association. Then his Grace passed on to review the early history of iron, the manufacture of which was mentioned by Homer and Hesiod, and had been asserted by Mr. Layard to have been known in Assyria in 900 B. C. He then noticed the early methods of manufacture dowu to the period of the use of coal, which gave such a vast impetus to the manufacture of iron in this country, and afterwards referred to the invention of the "hot blast," the increased supplies of ore, and other causes which had contributed to the present importance of the iron manufacture. The processes by which pig iron, malleable iron and steel are manufactured having been alluded to, the president referred to the utilization of the waste of gases from the blast furnaces, and went on then to show how the raw material and manufacture were distributed over the world. The problems to be solved now, which were of the most importance, were economy in the consumption of fuel, and a greater ultilization of the waste gases. Mineral oil had been used in the dockyards in place of coal. It was also highly important to obtain the metal as pure as possible, and though chemistry had been brought to the aid of the manufacture, yet the chemistry of iron and steel was still in many respects obscure and uncertain. His Grace concluded by a brief bu teloquent reference to the importance of iron as an essential necessary of civilized life. Mr. Richard Fothergill, M. P., moved a vote of thanks to his Grace for his address, and requested that it should be printed. Mr. Isaac L. Bell seconded the resolution, which was carried by acclamation.—*Engineering.*

Metal Product of Russia.—In Russia, in 1867, there were 1,211 iron smelting works, employing 87,086 hands, and yielding products valued at $92,042,918. The value of the manufactures of other metals is thus stated:—Silver, $2,205,164; lead, $3,791,840; copper, $2,991,552; brass, $1,-608,271; zinc, in bars or plates, $6,385,993; other zinc, $2,104,254.

PARTICULARS OF BLAST FURNACES.

Prepared by Dr. Thomas Egleston, jr., Professor of Mineralogy and Metallurgy, Columbia College School of Mines.

NOTE.—The dimensions are in meters = 39.38 in.

Precautions in Building Furnaces.—In the last two years some accidents have occurred during the erection of fnrnaces. We have examined the causes in several of these cases and have fonnd that they have been attributable to the following defects and oversights :

1. *Insecure foundations.* Some engineers are not practically aware of the exceeding pressnre and weight arising from the methods of constrnction in fnrnaces and in the hoists. Some of these structures, from the conditions under which they have been erected, require a small area of base with comparatively enormous superincumbent weight. Perhaps we might have made no distinction between pressure and weight, but we think it necessary to make what we apprehend is a true distinction in this case. By weight is meant that force of gravity applied at the juncture where the generally-considered homogeneousness of material terminates, and by pressure, the same force as applied in the general structure or material itself. Allowing this definition, we would say that the weight of some furnaces of moderate size creates a formidable amount of pressure upon foundations. Is it not therefore strange, that with the addition of material of the charges, cracks and injurics occur after, if not before the blowing in? We have seen some furnace and hoist-walls give way before they were quite complete. For illustration sake. let us suppose we weigh a furnace of 50 ft. high and 12 ft. bosh, bnilded of limestone, and put np in the usual way. As the stack will be filled with material whose average density will fully cqual that of limestone, or other rock used for this purpose, we may consider its specific gravity 2.7, water being 1. Taking the latter at 60 lbs. per cubic foot, we shall have fair data to bcgin with. Snpposing the above furnace to be only 20 ft. square, on the average, to level of tunnel head, and the weight of each cubic foot to be 162 lbs., we shall have a reasonable average weight. These elements would give a weight of 1,446 tons, and the soil (if builded upon soil), would receivc, if all things were uniform, a pressure of about 56 lbs. upon the square inch. It will therefore readily be seen how easily a hoist, or furnace stack, may be injured by the yielding of even a part of the foundation, causing, as we have seen in more than one instance, a crooked wall before any fire was kindled within the works. We were informed by a gentleman who had more than fifty years of experience in building, that small stones laid in the trench excavated for walls, were more secure as a first layer than large stones, and we were referred to a large and heavy stone structure, erected more than twenty years before, in which heavy machinery had been running since its erection, and not a crack of any kind was apparent. We saw the walls of this building after they had becn subjected to a very severe fire, but no crack madc its appearance, giving additional evidence that there was no weakness in the foundations. There is much practical philosophy, unnsual as it may seem, in the laying small stones down first and letting them rnn into the ground conformably to the under surface of the large fonndation stones used in furnace constructions and their accompanying walls and hoists.

2. *Improper building material.* We have seen only one illustration of unwise economy in this respect so far as furnace works are concerned. In this case the stack and hoists became useless after being nearly completed, because of the use of a friable sandstone, taken from near at hand to save hauling from a distance. The pressure was too great for the stone. Materials are improper when the individual stones are small, especially at the corners of the structure, and they should decrease in ascending, as a matter of preference, however, and not of necessity. It is a mistake to suppose that all limestones are unfit for furnaces. Some silicious stones of that nature answer admirably when protected from fire. The conglomerates, consisting of quartz pebbles cemented with sand and aluminous silicates, form an excellent material where the adhesiveness is sufficiently great. The conglomerates of the anthracite and other regions form excellent hearthstones, and have been used most efficiently for many years, as some sandstones have been also. The composing pebbles vary from large stones to smallest pebbles, and there is no difficulty in obtaining large masses. In some placcs fire clay bricks, of large size, have been used for hearthstones with satisfactory results.

Kaolin mortar, containing soda and lime, we have good reason to suspect, is inferior. The same may be said of the fire bricks made from such matcrial. Good kaolin mortar is generally fine in texture, with little grit, and generally hardens soon, and when dry, the mortar will not rub off in gritty particles. In putting up several furnaces we had a fair trial made of kaolin clays, or fire clay cement, and have found, thus far, that the clays containing no lime or soda and partaking of the nature of silicate of alumina only, appeared to set more firmly as a mortar and remain uninjured longer as bricks. The lime-kaolins are affected comparatively more rapidly than any other. Nothing but analysis can detect it, although we have seen some powdery kaolins which were lime-kaolins, and we have suspected that this peculiarity might owe its origin to the presence of lime or soda. But when properly mixed and subjected to strong heat in a smith's fire, then kaolins are easily tested. The above are the chief causes of defects in furnace building.—*American Exchange and Review.*

Blast-Furnace Engines at the Lilleshall Company's Works.—The beams are of the horsehead class, and are 30 ft. from center to center of cylinders, and they are cast of the Lilleshall Company's cold blast iron. Each beam is composed of two flitches about 8 in. apart, the thickness of the bosses for the main centers being 9 in. The beams are supported midway between the cylinders upon an entablature 3 ft. deep resting upon four massive columns, mean diameter 17½ in. The columns and entablature, as also the nozzles, are elaborately decorated in the Doric order. The spring beams. which are of pine, 20 in. by 12 in., pass through cast iron saddles upon the entablature, and rest upon the walls of the house. The beams are 4 ft. 8 in. deep at the center. The main centers are 21 ft. 6 in. above the floor of the house. They have journals 18 in. long and 10 in. diameter, and the pummer blocks are fixed on saddles upon the entablature, and are each held down by five bolts, one bolt 3 in. diameter passing down right through the column into the foundation. The main links are 4 ft. 3 in. long between end centers, with bearings 6 in. long and 4½ in. diameter, and the radius links are connected to studs carried by brackets fixed to the spring beams.

The steam cylinders are 40 in. diameter, with a stroke of 8 ft. 6 in. They are clothed with felt and mahogany lagging, and have an ornamental packing stage round them. The piston rods are of Bessemer steel, 4¾ in. diameter, and the pistons are fitted with metallic packing. The valves are of gun-metal, of the double-beat class 10 in. diameter, and are worked by cams keyed upon a horizontal shaft below the floor, which is set in motion from the crank shaft, through the intervention of a lay shaft and bevel gearing. The steam is cut off at quarter stroke. The air pumps are 29 in. diameter and 4 ft. 3 in. stroke, and are worked by rods attached to the beams midway between the center of the cylinders and main centers. The condensers are 29 in. diameter and 5 ft. 9 in. high, the eduction pipes being led into the top. To the other end of each beam, at a distance of 4 ft. from the main center, are attached three rods bracketed together, which work respectively two 6 in. feed pumps and one 14 in. cold water pump. The connecting rods are of massive oak between two wrought iron straps 5 in. by 1⅛ in., with ⅞ in. bolts through, and fitted at each end with cast blocks, brasses, gibs, and screw cottars. They are 27 ft. 5 in. between end centers, and are coupled to the beams at a point 13 ft. 4 in. distant in a straight line from the main center. The lower ends are coupled to cast iron cranks 5 ft. 2 in. throw, the crank pins being of hammered iron, with journals 6½ in. long and 5 in. diameter. The fly-wheel is 20 ft. diameter and nineteen tons weight; the rim, which is 8 in. by 18 in., is casted in one piece. The arms, eight in number, are blocked and keyed into the rim, and the other ends are turned to fit holes in the center boss to receive them. The center is bored and keyed on the shaft. The fly-shaft has journals 18 in. long and 13 in. diameter. The seat of the wheel is 14 in. diameter. The blowing cylinders are 86 in. diameter, and samo stroke as the steam cylinders, viz: 8 ft. 6 in. Inlet valves are placed in boxes on the cylinder covers and on grids in the cylinder bases, and their combined area at one end of the cylinder is 5¼ square feet. Outlet valves are placed in wrought iron boxes at top and bottom of cylinders. Their area at one end is 1.33 square feet. These valves are made of two thicknesses of leather sewn together; and as all the inlet and outlet openings are grated, no plates or weights are required, and the valves answer the piston readily, the result being a superior blast. The piston rods are of Bessemer steel 6 in. diameter. The pistons are packed with cotton gasket —which when set hard and lubricated with black lead is found to work satisfactorily—and are cast with loose segments for convenience of packing. The blast is supplied cold to five furnaces at a pressure of 3½ lbs. per square inch, the engines running seventeen strokes per minute, with a steam pressure of 35 lbs. The blast is delivered from cylinders into wrought boxes at top and bottom of cylinders, connected by a 3 ft. wrought iron pipe, and thence through a conical pipe to the 5 ft. main, which supplies the tuyeres. There is a large opening in the engine-house in the rear of the blowing cylinders louvre-boarded to admit the air to the inlet valves. The cylinders are all firmly bedded upon stone foundations, and are each held down by four 2½ in. bolts passing down 15 ft. below the floor.

The engine-house is 58 ft. long, 25 ft. wide, and is built of stone and brick, the walls being 3 ft. thick. The engines are supplied with steam by five Cornish boilers 31 ft. long, 7 ft. 7 in. diameter, each with two 3 ft. flues through, and are fired entirely by the waste gases from one furnace.—"*The Engineer.*"

Economizing Fuel in Blast-Furnaces.—After standing for more than six months for alterations, and the putting down of new machinery, the Wingerworth Furnaces, near Chesterfield, are once more at work. Their appearance, however, is very different to what it was before the improvements to which we are about to allude took place. The old furnaces gave out the usual smoke and flame from the top, but at present, on passing, it is difficult to say whether they are in blast or not, so free are they from the usual indications one looks for. This result has been attained by taking the gas from the top, and utilizing it in a simple yet efficient manner. To effect this object, new boilers, heating-ovens, and gas apparatus, have been put down at considerable expense. The gas is conducted by a pipe to the bottom of the furnace, from whence it is sent into the boilers and heating-stoves, and there consumed instead of coal. The blast of the furnace is heated to a temperature of from 900° to 1000°, without the use of any coal whatever. The gas is taken from the top of the furnace by a process similar in many respects to that adopted at some of the works in the North of England, but somewhat different as to the mode of conducting off the gases. The alterations have given the most satisfactory results, the produce of iron from the same quantity of ore being considerably larger than by the old method, whilst the quality is also superior. The saving in fuel—an item of so much importance—has been something enormous, making a difference of many tons of coal per week, yet doing the work more efficiently. The alterations and improvements were suggested by Mr. Gjers, of

Middlesborough, and ably carried out by Mr. Marsh. The boilers, which are arranged for being worked by gas were made by the Parkgate Company. The cost of the alterations, which is considerable, will soon be repaid by the great saving in fuel, and the superior quality of the iron produced. From the many advantages of the system we think it is worthy of the consideration of iron makers in all parts of the kingdom—more especially in those districts where coal and coke have to be imported from a distance.—*Mining Journal.*

RAILWAY NOTES.

The Railways of India.—A great deal has been said and written respecting the completion of the Pacific Railway across the American continent, and much praise has been very justly bestowed upon the energy of the American character which has brought the work to its present position. While, however, we are lavish in our expressions of admiration for the great qualities which have thus been called into existence, we ought not to lose sight of the still greater works which have been accomplished in India, in the matter of railways. A vast work has been carried on silently and unobtrusively, and under difficulties even greater than any which have been experienced in regard to the Pacific Railroad, and we claim for those by whom these great works have been achieved some share of that admiration which is given so freely and so fairly to our American cousins.

The Pacific line, including as it does the two separate schemes of the Union Pacific and the Central Pacific, is about 1,700 miles in length. Two of our leading Indian lines, viz : the East Indian and the Great Indian Peninsula, at present in work, have a joint mileage of 2,230 miles, and when completed it will be 2,768 miles, greater by more than one-half of the whole length of the Pacific road. Like the Pacific, these lines cross our Indian empire from east to west, and connect Bombay and Calcutta, just as the Pacific forms the connecting link between San Francisco and New York. By means of the East Indian a railway connects Calcutta with Delhi, more than 1,000 miles distant from each other; in the south, Madras and Baypore are connected by a line crossing Southern India; Nagpore, in Central India, is connected with the port of Bombay; by means of the flotilla and Punjaub line, Lahore in the northwest, and Kurrachee in the Indus are brought into direct connection with each other. There are now actually completed and at work in India, 3,942 miles of railway, or about 600 more than the whole mileage between New York and San Francisco, and there remain to be completed of lines already sanctioned 1,665 miles. This great extent of railway has been constructed in a country many thousands of miles distant from England, where, with a trifling exception, the whole of the capital was provided. For the construction of these works there was required to be shipped from this country 3,529,000 tons of goods, of the value of £23,252,000, and which was conveyed in 5,339 ships. In America no such difficulty as this was experienced. The road, as it was formed, was enabled to carry the iron and timber required for the construction. The contractors worked from an already organized base of railways at home; the materials for the Indian lines had to be borne over thousands of miles of a sea voyage.

In both cases the Government of the country gave valuable aid to the great works. The United States Government issued their 6 per cent bonds at the rate of about £3,000 for each mile completed. In India, the Government gave its 5 per cent guarantee on the capital required. The Government of India has already paid as interest on the capital subscribed a total of £22,212,000. The amount of pecuniary assistance given by the United States Government, although large, must have been considerably less than that paid by the Indian Government, the whole amount of bonds issued not greatly exceeding £5,000,000 sterling. Of the amount paid by the Government of India in the shape of guaranteed interest, £9,500,000 has been already repaid out of the earnings of the railways over and above the guaranteed interest. The balance is to be repaid out of the half surplus profits over 5 per cent, and, judging from the results already obtained, a few years will suffice to clear off this amount of indebtedness. The position of the United States Government is by no means so favorable, as it appears that the amount of the Government bonds has been overlaid by the bonds of the company, which take precedence of the Government advances.

The construction of the Indian railways has presented difficulties of a much more formidable character than those which have been met with on the Pacific line. It is true that this railway has been carried over vast plains and mountain ranges of which little was known, and in the face of the attacks of hostile Indian tribes. In India, the works were carried out in the face of difficulties connected with the oppressive heat of the climate—through forests and jungles which were the resort of savage animals, and the people employed were natives of the country, speaking a language unknown to those by whom they were employed, and whose habits and modes of life unfitted them for labor such as that on which they were engaged. Great works such as those of the Bhore Ghaut and Thull Ghaut inclines presented difficulties equal to, if not greater, than any experienced in the crossing over the Rocky Mountains. Streams wider and more rapid than met with between Omaha and San Francisco have been successfully bridged, and present some of the greatest triumphs of modern engineering science.

While congratulating ourselves upon the results attained, so far as they affect the national character, it is not less a source of satisfaction to see how great has been the benefit already derived from railways in India. Ten years since the time occupied in traveling from Calcutta to Silma was four weeks —it took four months to march a regiment between those places; the distance is now traversed by a railway in five days. Last year 13,746,000 passengers traveled upon the Indian railways. It is worthy of notice that of this number not less than 13,074,000, or within about 700,000 of the whole number conveyed, were third class passengers. The total sum paid by railway travelers was £1,376,000. The goods traffic upon the whole of the railways yielded £3,320,000 of gross revenue. Those scruples of religion and distinctions of caste which have been for so many ages the bane of Indian society are fast disappearing before that mighty leveler of the age—the locomotive. Separate carriages or compartments were in the first instance provided for women, in deference to the feeling of dislike universally entertained at wives or daughters being seen by strangers; separate accommodation for different castes was also provided. Now all is changed, or rapidly undergoing a change. Brahmins, too, of the purest blood, travel in the third-class carriage, huddled in crowds with the most wretched Pariah, whose very presence near the household roof would in former times be regarded as the most deadly pollution. Railways, too, have been of immense service in encouraging the cultivation of cotton and other produce, in the working of iron and coal mines, by the facilities which they have afforded for bringing the produce to good markets and convenient ports for shipment. The merchant is enabled by means of the railway to deal directly with the cultivator of cotton and grain, and by this means increases the profits on their mutual transactions.

For the carrying on of the traffic upon the 3,942 miles of railway in India, there are now 937 locomotives, 2,733 passenger carriages, and 18,226 trucks and wagons, making a total of 20,959 vehicles. From the able report of Mr. Juland Danvers, we learn that there are employed on the railways of India not less than 39,099 persons, of whom 36,048 are natives.

The entire capital of £75,000,000 has been provided by 58,346 proprietors of stock and debentures, giving an average holding of about £1,300 each, and affording to them an investment scarcely less secure and much more remunerative than British Government stock. The capital estimated to be required for completing the railway system so far as it is at present sanctioned is £93,916,000. Of this sum authority has been given to raise £84,386,000, and the amount actually raised to the close of the last financial year was £76,579,000.—*Railway News.*

Railroad Frogs.—There is no portion of the permanent way of a railroad subjected to harder usage than that part of it where frogs are placed, for the purpose of effecting a crossing from one track to another. At these points the wear and tear is always more than double that of the ordinary track, and the existence of a frog has, at the best, been a precarious one, and often times but very short lived. From the primitive frog made from wrought or cast iron, we advanced to frogs with cast-iron bed plates plated with steel, riveted or bolted on, while others were of wrought-iron with movable wing rails and steel points. Then there were frogs made entirely of cast cast-steel and so arranged that when the top face of the frog was worn, it could by being simply overturned be made to live as it were, a double life. Each frog has in its generation been considered more economical than its predecessor, yet, even those of cast cast-steel—probably offering greater advantages than others preceding them—have the same objection as all cast frogs and are liable to crush under heavy weights, or break with concussion or when subjected to the effects of the severe winters of this country.

A hammered steel frog lately patented in America by Messrs. Armstrong & Co., Steel and Iron Works, Rotherham, Yorkshire, and 43 Exchange Place, N. Y., appears to possess advantages in strength and durability that other frogs do not have, and the testimony of many of the leading engineers in Europe, where the frog has been in use for three years without showing the slightest wear, leads to the believe that it is the best frog yet introduced.

The frog, as has been stated, is made from hammered crucible cast-steel, drawn from the ingot without a weld. It is reversible; is finished in the planing machine and is perfectly true to the required angle. It will neither crush nor break under heavy weights, nor with trains running at great speed. Its reliability is not decreased when subjected to severe frosts, and being of hammered metal, its elasticity prevents the rigidity felt in running over all cast crossings. When the frog has fulfilled its first purpose, the metal being necessarily a good mild steel, to bear hammering and planing, it can be sold for a large proportion of the first cost or can be converted into forgings or rolled into sheets. From a monetary point of view, this frog is more economical than the ordinary steel frog cast in moulds and, apart from this consideration, its durability is probably more than double and the reliability much increased. These frogs are also made non-reversible, an arrangement which materially reduces their first cost without decreasing their other advantages.

Messrs. Armstrong & Co. have also patented a frog composed of a cast iron bed plate with a working face of cast cast-steel. This steel facing is not riveted or bolted on, but in the process of manufacture, the two metals are incorporated, and the frog is complete in one casting. In practice it has been found, that frogs thus made are much sounder than the ordinary cast cast-iron frog and are insured perfectly free from blow-holes. They possess the recommendation of being low priced and durable. C.

Railroad *vs.* Railway.—A correspondent offers the following considerations: The use of rail*way* for rail*road* is improper—the English speaking public to the contrary, notwithstanding. The question lies in the appropriateness of *way* or *road*. The following passage from Crabbe's Synonyms, a book of the best authority, will help us in our determination.

"*Road* comes no doubt from *ride*, signifying the place where one rides. *Way* is the generic term; it is the path which a person chooses at pleasure for himself.

'He stood in the gate, and asked of every one
Which *way* she took, and whither she was gone.'
Dryden.

The *road* is the regular and beaten *way*."

Let me also quote from Gray's Synonyms, page 52: "Way is the general term, and road is the species of way. Instead of keeping the high-road to a town, you may frequently go a shorter way across the fields."

When we Americans coin a term that is correct, we should not give it up and use another because it comes from England.

Color Blindness and Railway Disasters.—One cause of railroad accidents has been discovered in England. It is what is known as color blindness. An engineer ran his train into another, causing great damage. On investigation it was found that he could not distinguish red from green, and had mistaken the signal lights.—*Exchange.*

We have an excellent way of avoiding such disasters in America—not having any signals at all.—*Ed.*

Bridges on the Pacific Railway.—Over 50 new bridges to replace temporary bridges on the Union Pacific Railroad have been built at Chicago and shipped and put up this season, and new ones will be completed over the whole line in 60 days.

Railway Consolidation.—Consolidation, which for a few years past has been the leading feature in railway strategy, is now operative upon the grandest scale. The Pacific route has given a fresh impetus to the plans by which "through bnsiness" can be facilitated and opposition set aside.

The recent combination of the roads between Boston and Albany under one direction, the plan now maturing for uniting all the lines, finished or unfinished, from Boston to Oswego, the union of the Lake Shore and the Cleveland and Toledo companies, the successive purchases and consolidations of stock by which the Chicago and Northwestern, and the Milwaukee and St. Paul railroad companies have grown to their present importance, are all examples of the rapidity with which the idea is gaining ground. These consolidations have practically enabled two great companies to control all transportation on the great middle link, *i. e.*, between Chicago and Omaha.

It is further proposed to unite in one company and under one management a continuous line of railway from New York to Omaha. This proposed corporation is to hold and administer the property and franchises now held by the Hudson River, the New York Central, the Buffalo and Erie, the Lake Shore and Cleveland and Toledo, the Michigan Southern, and the Chicago and Northwestern Railroads, including 2,480 miles of completed and equipped railway. The gross income of these companies for last year was $44,820,893.

The Pennsylvania Railroad Company leases the road of the Pittsbngh, Fort Wayne, and Chicago Railway, with all its branches, for 999 years, commencing July 1, 1869. By the terms of the lease, the former company agrees to pay the interest on the debt of the latter, and in addition thereto the sum of $1,380,000 per annum as rent for the property. The capital of the Fort Wayne Company is $11,500 000; consequently the snm of $1,380,000, named as the annual rent, is 12 per cent on the capital. The directors of the P., F. W. & C. propose to increase the amount of their stock, making the annual rent 7 per cent on the capital as increased. The P., F. W. & C. is itself a consolidation of three original companies, whose lines conjointly connected Pittsbnrgh and Chicago. It became involved in debt, and in 1861 was sold under foreclosure, the present company becoming the purchasers in 1862. This is but one step in the purpose of the Pennsylvania Railroad Company, but all reports as to other consolidations have no authority.—*American Exchange and Review.*

Turkish Railways.—In view of the great expansion of commerce which the Suez canal and the Turkish railways will create in the empire, it is proposed, among other works of magnitude, to make spacions harbors for the chief seaports, such as Constantinople—which is totally without accommodation of this kind—Salonica, etc. As regards Turkish railways, the nearest connecting point with Austria will now be Sissek, and not Brod, as formerly. Here the junction with the Southern line will be effected, and by this means the route to Trieste and Fiume, as also to Vienna and South Germany, *viâ* Northern Italy, to Southern France, will be accomplished. In the other direction the State Railway from Gross Kikinda to Belgrade will be constructed, and thence be connected with the Servian Railway.

Tests of Steel and Iron Car Wheels.—We have been furnished with the minntes of some tests made upon a cast steel car wheel, Tarr's patent, made at the "Black Diamond Steel Works," at Pittsburgh, Pa., and tested at the shops of the Pennsylvania Railway at Altoona, June 26, 1869. The test was that of the drop, weighing 1,200 lbs., falling upon the wheel, placed on bearings two feet apart, the blow on the hub :

1st blow,	9	feet	fall,	no	apparent	injnry.
2d "	11	"	"	"	"	"
3d "	14½	"	"	"	"	"
4th "	16	"	"	"	"	"
5th "	20	"	"	"	"	"
6th "	28	"	"	'	"	"
7th "	28	"	"	cracked at hub.		
8th "	28	"	"	drove hub through the plate		

of the wheel, leaving the whole tread and guard around the circumference of the wheel perfectly sound. The steel wheel weighed 444 lbs.

At the same time and place the following tests of the best iron wheels in use were made :

Ramapo,	1st	blow,	10	feet,	broke	in	many	pieces.
Lobdell,	1st	"	7	"	"	"	"	"
"	2d	"	10	"	"	"	"	"
German,	1st	"	7	"	"	"	"	"
Whitney,	1st	"	5	"	"	"	"	"
"	2d	"	7	"	"	"	"	"
Whitney,	1st	"	7	"	"	"	"	"

The cast cast iron wheels weighed 550 lbs. each. These tests are rather crude in character, but they establish the fact, pretty well known before, of the superiority of cast steel over cast iron, in resisting the effect of hard blows. A well made cast iron car wheel has an endurance on the track almost wonderfnl, but if the steel is better, safer and as economical in the end, let it be adopted by all means. At any rate let us have the real wearing tests made under the cars, and then the economical questions are easily solved.—*Railway Times.*

New Rail-Leveling Device.—The ordinary lever-bar used for lifting rails and sleepers in constructing and repairing the permanent way of railways, involves in its operation the labor of several men. To obviate this, an English engineer, Mr. De Bergue, has constructed a simple and compact tool, composed of a kind of shoe combined with a bar pivoted at one end, and at the other furnished with a screw by which it may be raised relatively to the shoe. The instrument with its bar depressed is thrust under the rail or sleeper to be raised, and the screw is turned until the bar has been forced upward sufficiently to bring the superincumbent parts to the required position. Those portions of the apparatus subjected to heavy strains are made of steel, and the working surfaces are hardened so that it cannot easily get out of repair. —*Railway Times.*

The Sliding of Car Wheels.—An experiment has been made at Munich, for the purpose of determining if a railway-carriage wheel rolls regularly without sliding, so that by recording the number of revolutions of a wheel, the circumference of which is known, the distance accomplished could be accurately ascertained. The difference between the measurement by mathematical instruments and that obtained by noting the revolutions of the wheel, was found to be no more than 1-68,000 of the whole.

WOODEN WHEELS.—Mansell's patent wheels for railway carriages are fast coming into general use. They have already been adopted by the London and North-Western, Great Western, Midland, Great Northern, Great Eastern, Metropolitan, and other English lines, and the Imperial Government has sanctioned their adoption on all the railways of Russia. It may not be generally known that Mansell's original patent was for securing the tire to the wheel by retaining rings, the fillets of which are turned to fit into corresponding grooves in the tires. The whole is secured by nuts and bolts. Between the tire and the boss, spokes are dispensed with by the insertion of stout close-fitting panels of East India teak wood, the oily nature of which preserves from oxidation the iron passing through it. For this purpose teak is superior to any other wood and it has further the advantage of never shrinking. The superiority of these wheels over iron ones is well known to all observant travelers, their special merits being absence of jarring, and also of noise.—*The Engineer.*

IRON TUBES FOR BOILERS.—There are many lines of railway on which iron tubes are found to answer as well as brass, if indeed, they do not answer better. We believe iron tubes are very largely used on the Lancashire and Yorkshire Railway, and with good succ ess. A single Birmingham house might be mentioned which has turned out 550 tons and upwards of iron tubes a month, and of these as many as 10,500 have been for locomotives, corresponding to perhaps sixty locomotives in number, although it is not to be supposed that a single house has gone on at the same rate for a year together, iron tubing, in that time, as many as seven hundred or more locomotives.—*Engineering.*

DURABILITY OF ENGLISH LOCOMOTIVES.—The life of a locomotive boiler has been found to be about 350,000 train miles, but this may probably on some lines go up to 400,000, or even 500,000 miles, as its wear and tear would depend greatly on local circumstances, and particularly on the chemical qualities of the water employed. Assuming that the life of the engine is determined by the endurance of the boiler, and that if, under favorable circumstances, it will last the 500,000 miles, then during that time the fire-box will probably require to be renewed at least three times, the tires of the wheels five or perhaps six times, the crank axles three or four times, and the tubes probably from seven to ten times.—*Herepath's Railway Journal.*

ANOTHER ALPINE RAILWAY.—Mr. Thomas Brassey, the railway contractor, has just completed his tour of inspection over the projected new railway from Innspruck, *viâ* Feldkirch, to the Bodensee, and that his opinion seems to incline in favor of the improved Fell system over the Arl mountain, instead of tunneling through it. We trust, however, for the sake of the shareholders, that there is no foundation in the report. Our own opinion of the Fell system is well known.—*Neue Freie Presse.*

CAR LOCKING IN ENGLAND.—Mr. Bentinck is about to bring under the notice of the House of Commons the practice adopted by railway companies of barring the windows and locking the doors of passenger carriages.

NEW BOOKS.

A TREATISE ON THE ART OF CONSTRUCTING OBLIQUE ARCHES WITH SPIRAL COURSES. By WM. DONALDSON, M. A. Cant., Assoc. Inst. C. E. London: E. and F. N. Spon, Charing-cross. For sale by D. Van Nostraud, New York.

The importance of works the object of which is to enable the practical man to proceed with mathematical accuracy in his business, without requiring to undertake the labor of studying pure mathematics, is more extensively acknowledged every day; whilst the continually increasing attention paid to technical knowledge by business men enables strictly scientific men to afford them the necessary theoretical aid with far greater facility than formerly. A very valuable treatise of the technical science class has just been issued by Mr. Donaldson, and will, doubtless, find a large number of patrons. The object of the author has been to arrive at a series of formulæ which would give the data necessary for the construction of oblique arches, without having recourse to any developments on a large scale, or which require skill in draughtsmanship.—He commences by explaining and demonstrating the properties of screw surfaces, and then proceeds to investigate the stability of oblique bridges, basing his investigations upon the assumptions—firstly, that the material can resist any pressure that can be put upon it; and, secondly, that for perfect security no force of shearing must be exerted upon any of the voussoirs. He explains that the forces acting on a voussoir are its own weight, a portion of the weight passing over the bridge, and the pressures on its beds. No force is exerted on the ends of a voussoir; in oblique bridges it is kept in its place by the friction on the beds. If there were no backing these forces must be in equilibrium; this is never the case where the live load is variable; they must, therefore, have a definite resultant.—We may resolve these pressures in three directions—vertical, parallel to the axis, and perpendicular to these two; the resultant of the vertical components will be eqal and opposite to the weight of the voussoir and the weight upon it, and in order that the horizontal components may satisfy the condition for perfect safety, their resultants must fall within the springing nearest to the bed to which they refer, so as to meet the material with which the bridge is backed up; also, since the pressures between the voussoir beds are mutual, the horizontal resultant of each pair must pass within each springing. He explains that the pressure at any point of a voussoir bed will act in the direction of a normal to the surface at that point, and will, therefore, lie in the normal plane to the screw line passing through that point, and will also be perpendicular to the revolving radius; and, therefore, its line of direction will be the line of intersection of the above normal plane, and a plane through that point perpendicular to the radius—the pressure at every point along this radius may be assumed to be the same. Having disposed of the question of the stability of oblique arches, Mr. Donaldson treats of the formation of templates. All the formulæ previously proved are collected together and their use explained, by working out the details of a bridge, an angle of forty-five degrees being chosen, because an instance in which the skew is very great gives the best illustration of the errors introduced by the approximate methods used. Throughout the book Mr. Donaldson displays not only an intimate knowledge of the subject on which he writes, but also a great ability in imparting that knowledge to others. The work is strictly mathematical, but a knowledge of logarithms only, and this may be acquired in five minutes by those who do not already possess it, will suffice for the practical application of the formulæ.

SOUND. By JOHN TYNDALL, L.L. D., F. R. S., Professor of Natural Philosophy in the Royal Institution of Great Britain. Second Edition. Longmans, 1867. For sale by D. Van Nostrand, New York.

That this book should have reached a second edition so soon after its appearance, does not surprise us; for even to unscientific and unmathematical readers the abstruse subjects connected with natural philosophy become not only intelligible, but fascinating in the hands of Professor Tyndall. Since the death of Faraday, Tyndall has no rival as a master of experimental science, but even Faraday was not able to set forth his philosophy in the same picturesque and charming style as his successor. At once profound and popular, elaborate yet simple, abounding with beautiful illustrations, curious truths, and striking descriptions, these lectures are in the deepest sense instructive, and in the highest degree entertaining. The work has not only excited the attention of the scientific world generally, but has won admiration from all quarters. Besides the flattering reception it has met with in this country, the book has been republished in America, while editions of it have appeared in France and Germany.

The readers of these lectures must necessarily labor under no small disadvantage as compared with those who heard them delivered and witnessed the beautiful experiments by which the subject received elucidation. But this drawback notwithstanding, the reader will still find it a delightful task to follow Professor Tyndall through his curious labyrinth of reasoning and experiment in these pages. As he himself tells us, the true physical philosopher never rests content with an inference when an experiment to verify or contravene it is possible. Accordingly, the science of acoustics is here treated experimentally throughout, and the lecturer has endeavored so to place each experiment before the reader that he may almost realize it as an actual operation. No fewer than 169 illustrations of experiments accompany the text. In a word, to give distinct images of the various phenomena of sound, and to cause them to be seen mentally in their true relations, has been Professor Tyndall's task. He has not only succeeded, but has given the world by far the most complete and valuable contribution to the science and literature of acoustics that has appeared.—*The Building News.*

WROUGHT IRON BRIDGES AND ROOFS. By W. CAWTHORNE UNWIN, B. Sc., C. E. London: Spon, 1869. For sale by Van Nostrand.

This volume contains a series of lectures delivered at the Royal Engineer Establishment, Chatham, to the officers of the Royal Engineers under instruction there; and they were afterwards printed at the press of that establishment for private circulation. That they proved useful to those for whom they were originally intended we have no doubt, and they are now offered in a revised and rearranged form to a wider circle of readers. The author assisted Mr. William Fairbairn in some of his many researches, and the work is dedicated to him. It is illustrated with examples of the calculation of stress in girders and roof trusses by graphic and algebraic methods. The author has restricted the use of symbolic expressions as much as possible; and the work holds an intermediate place between practical and theoretical treatises.—*Builder.*

TRAITÉ DE l'EXPLOITATION DES MINES DE HOUILLE etc., etc. PAR A. T. PONSON, Ingénieur civil. 2nd Edit. by JULES PONSON. Liège and Paris. 2 vols. and Atlas.

This able and complete work on coal-mining has been somewhat improved in this its second edition. It is a tolerably exhaustive treatise from the Belgian point of view of its entire subject; not better, however, than one or two French works on the same which we have ere now reviewed in these pages.

In one of its most interesting and important sections, that on shaft-sinking through water-bearing strata of running sand and mud, we observe with surprise the absence of any notice of some of the most ingenious and effective contrivances that have advanced this part of the pit-sinker's art; and this is the more remarkable, as these are of origin so close to Belgium as to be almost Flemish. The Atlas of Plates published along with the first volume, which is all we have as yet received, is well executed, and the details, both as to coal formation and the tools etc. for working coal clear and good.—*Practical Mechanics' Journal.*

TRAITÉ PRATIQUE DE l'ENTRETIEN ET DE l'EXPLOITATION DES CHEMINS DE FER. PAR CH. GOSCHLER, Ing. etc. 8vo. Baudry, Paris. 1868.

This able systematic work upon the maintenance and working of railways, the two first volumes of which we reviewed a good while ago, has now reached its third and fourth, or concluding volume. The two first, it will be recollected, treated of the material and *personnel* of railways; now we have their keeping in repair and making good use of them systematized and treated of with clearness and great practical ability.

The work ought to be a *vade mecum* to every chief servant in the employ of every railway in Great Britain, or at least all such would profit by its study; but for this a translation into English must be had, and we see on the title-page *tous droits réservés.—Practical Mechanics' Journal.*

THE DISINFECTANT QUESTION. London: M'Corquodale & Co. 1869. For sale by Van Nostrand.

Who shall review the reviewers? This question arises to us because the little work before us is a reprint of a review published in a journal called the "Sanitary Record," upon a book on disinfectants recently written by Dr. Angus Smith. The work is virtually a defense of Condy's disinfecting fluid as against McDougall's powder, which the writer says, was partly invented by Dr. A. Smith, who is therefore likely enough to speak well of it. We do not like the tone or temper of the writer. But we must confess that our experience leads us to have a great faith in the value of permanganate of potash, whether it be sold by Mr. Condy or not. It is a most valuable disinfectant and deodorizer, and when used in extremely dilute solution as a gargle, it is one of the best detergents in cases of sore throat and quinsey. Mr. Condy did not discover the permanganates, but he has certainly been instrumental in introducing them into sanitary use. His "fluids" are essentially permanganates, and they are sold in a more convenient form and at a cheaper price than they can be obtained from the chemist. This fact may in some measure justify the writer's severe strictness on the slur which Dr. Smith has cast on "Condy's fluid."—*Scientific Opinion.*

A Practical Treatise on Mill-Gearing, Wheels, Shafts, Riggers, &c., for the Use of Engineers. By Thomas Box. London: E. and F. N. Spon. For sale by Van Nostrand.

All those of our readers who possessed of Mr. Box's "Practical Hydraulics" and "Treatise on Heat" (and no engineor should be without those handy little volumes) will gladly note the publication of the work before us. Mr. Box's books are what they profess to be, practical treatises clearly written and free from all abstruse mathematical formulæ; while they are, moreover, got up in good style, and are of a convenient size for reference.—The third of the series (at least we hope that there is to be a series), bearing the title at the head of the present notice is in no way inferior to those which have preceded it. It contains, within the space of some eighty odd octavo pages, five chapters, treating respectively of the standard unit of power, of wheels, of shafts, of riggers, and of keys for wheels and riggers; the work being concluded by an Appendix. In the chapter on wheels, Mr. Box gives rules for laying out and calculating the strength of teeth, as well as for proportioning the wheels themselves, these rules being accompanied by numerous tables, which materially facilitate calculation. Similarly the chapter on shafts comprises rules for calculating the transmitting power of shafts under different conditions, together with descriptions of various methods of coupling, useful notes on plummer blocks, bearings, &c., and a section devoted to the consideration of crank shafts for driving pumps and other work. The chapter on riggers or pulleys contains a clear explanation of the action of belts accompanied by some useful tables, and also rules for the proportion of riggers of various kinds; while the fifth chapter, though brief, is equally good in its way. Finally, the Appendix contains notes on the contraction of wheels in casting, the strength of shafts and gearing for screw propellers, and the theoretical strength of shafts.

We have now briefly indicated the contents of Mr. Box's useful little treatise, and we trust we have said enough to show that it forms a valuable addition to the practical engineer's library.—*Engineering.*

The Handbook of Iron Shipbuilding. By Thomas Smith, M. I. N. A. London: E. and F. N. Spon.

It is, unfortunately, seldom that we find men eminent in their profession willing to benefit the public by their knowledge which has been acquired during many years of varied experience. It is, indeed, too generally the fact that such knowledge is jealously guarded by them, and the only method by which any one can acquire it, is to undergo similar training, and, by picking up a "wrinkle" every now and then, gradually to become proficient. In this case, however, the author, with a generous independence that cannot be too highly praised, and which evidently arises out of a certain consciousness of superiority in his profession, has given to the public a large amount of exceedingly useful information which has hitherto been most religiously kept secret. Although this work is but small, it appears to teach everything that is requisite for building an iron vessel; not only giving dimensions and a full textual explanation of every part of a ship, from the keel to the framing of the hatches, but illustrating such of these explanations as may require it, by simple drawings that it is impossible to misunderstand.

In the second part of the work, besides tables of weights and results of experiments upon the strength of ships' beams, a vast amount of information is given as to the cost of vessels of various sizes, both as regards material and wages, every detail, even to the fitting up berths, being priced separately. The author has foreseen an objection that might be urged against the usefulness of giving prices—viz: that the price of labor varies considerably in different districts—by giving examples of the cost of labor on an iron vessel, not only in London, but also on the East coast, at Liverpool and on the Clyde; thus making this portion of the work equally useful for all parts of the country. From what we have said, it will be seen that we esteem this book very highly, and consequently we strongly recommend it to all shipowners, shipbuilders, inspectors, shipmasters, foremen, and all who wish to know how a ship ought to be built or what it ought to cost.—*The Artisan.*

Der Practische Maschinen Constructeur.—A German periodical for builders of machines, engineers and manufacturers, edited by Wilhelm Heinrich Uhland, engineer and director of the Technical Institute at Frankenberg-Chemnitz, in Saxony. This excellent periodical which has entered its second year, occupies itself principally and almost exclusively with the design and construction of machines of every description. It appears twice a month. Every number contains two large cartoons printed on both sides, with beautiful partly colored drawings of machinery of the best and newest construction, general plans as well as full and explicit details, so that no manufacturer or engineer of some experience will find any difficulty in making direct practical use of them. The whole character of this periodical is, in general, eminently *practical*, abstaining from all theoretical speculations, and plainly showing the way certain kinds of machinery or certain parts of machines have to be constructed and to be put in place to give complete satisfaction to makers and uses. As but very few papers of this character exist, and as the "Maschinen Constructeur" fills its task perfectly and steadily, we do not wonder that, in spite of the short time of its existence, this paper has already acquired a vast circulation in all industrial countries. Constructors, engineers and manufacturers, even when they are not acquainted with the German language, will find the various drawings of a high value.

What is Matter? By An Inner Templar. London: Wyman & Sons. 1869. The author of this work tries to answer a question on which, as we have no testimony of a crucial nature, it is absolutely impossible to decide. Whether the substratum of phenomena be regarded as either force or matter is really of no consequence. In either case when we go beyond the mere phenomenon—the mere sensual perception—we get into the land of metaphysical abstractions. We may explain the mental impression which our senses have originated by supposing it to be the result of force or forces, or of matter having certain pre-supposed qualities, or by any other equally ingenious hypothesis; but we are as far from demonstration as ever. We confess we fail to see that "An Inner Templar" has advanced one step nearer the solution of the difficulty than those who preceded him. We have not been able, either, to ascertain very satisfactorily whether he advocates the existence of matter or force. We are quite willing to concede either to him, as being a convenient method of explaining things whose explanation we really know no more of than we do of eternity, or infinity, or atomicity. But we cannot admit, and the writer will agree with us in this, both force and matter. If in imagination we abstract force from matter, there is nothing left to conceive of. "An Inner Templar" has made no actual observations in physics, and he says he objects to mere hypotheses, as Newton did. We hope he does; but, certainly, of all the startling and wild hypotheses that we have ever met with, his own hypothesis of the origin of the salt of the sea is the most wonderful, since it is clearly evolved, like the camal of the psychologist, out of his moral consciousness. To assert as probable, that the salinity of the sea is due to the perpetual emanations of sodium, in the form of particles of matter (light) streaming from the sun, throws the old story of the "mill grinding salt" for ever into the shade. We fear a "Templar's" love of speculation drives him sometimes beyond the dull and commonplace, though still useful, region of facts. Nevertheless, we think his book contains a deal of interesting matter.—*Scientific Opinion.*

WORSSAM & CO.'S ILLUSTRATED CATALOGUE OF WOOD-WORKING MAHINERY, OAKLEY WORKS, KING'S ROAD, CHELSEA. Folio, 1869. Illustrated.

This is one of the most copious, complete, and handsomely got-up trade catalogues of any British tool-making establishment that we have seen. Dimensions, weights, speeds, power to drive, work done per hour, &c. by most of the tools are given, and the Catalogue is really a very good and valuable practical guide to wood-working machinery of the best and most recent descriptions.

Although by title limited to wood-working machine tools, in reality it is still more comprehensive, and embraces punching-presses, crab and crane machinery, marble-sawing and grinding machinery, mortar mills and several others, which the issuing house have made their specialities.—*Practical Mechanic's Journal.*

THE STEPPING STONE TO ARCHITECTUE. By T. MITCHELL. Longmans. For sale by D. Van Nostrand, New York.

This little book forms one of what the publishers designate their "Stepping Stone to Knowledge Series," addressed to the young. It may be called a Catechism of Architecture, after the manner of the well-known Pinnock, being a series of questions and answers on the history and different orders and styles of architecture, ancient, mediæval and modern, "compiled with the view of creating a taste in the mind of the young for the noblest of the arts."—The publication, however, may also prove serviceable to some who are more advanced, since it gives upwards of a score of plates, and about fifty figures taken from "Gwilt's Encyclopædia of Architecture."—*Building News.*

A DICTIONARY, PRACTICAL, THEORETICAL AND HISTORICAL, OF COMMERCE AND COMMERCIAL NAVIGATION. By the late J. R. M'CULLOCH. With a biographical notice. New edition by Hugh G. Reid. Longmans. 1869.

This is a new and enlarged edition of a standard work, containing not less than 1,600 pages of matter. It is well spoken of by the English authorities.

INVENTORS' AND MANUFACTURERS' GAZETTE. E. H. SALTIEL, New York. This is a new dollar monthly, containg ten pages of text and many wood engravings.

MISCELLANEOUS.

JOHN A. ROEBLING.—Mr. Roebling was by birth a Prussian. He was a distinguished pupil of the Royal Polytechnic School of Berlin. The subject of his thesis, upon graduating from that institution, was "Suspension-Bridges"—a subject which made his after life famous, his death glorious, and which will give to his memory a fullness and freshness that cannot pass away. After having been engaged for three years, in accordance with a Governmental regulation, upon the public works in Germany, he emigrated to America. Arriving at Pittsburg, he settled upon a small tract of land, and devoted his attention for a while to agricultural pursuits. About the year 1830, the onward movement in the tide of American engineering affairs set in with all its force, and the young agriculturist was taken up by the first incoming wave. The plough and the harrow, the scythe and the sickle must needs give way to the compass and level, the rod and the chain. He was employed for some time on the various canals and other works at that time being carried on in every direction. With great forethought, he commenced the manufacture of wire-rope, doubtless instigated thereto by a recollection of his early love of the subject of suspension-bridges. The year 1844 records his first work of that class—to wit, the construction of a wooden aqueduct across the Alleghany River, which he carried out on the wire-rope suspension principle, with great success. The construction of the suspension-bridge over the Monongahela at Pittsburg, the site of his early agricultural labors, followed. The erection of suspension-brigdges in various localities so far enlarged his experience as to induce him to undertake the apparently impossible task of spanning the Niagara, near the falls, with a railway suspension-bridge. This, his greatest achievement, was completed in 1855, and, for boldness in conception, economy in construction, and proportionate strength in all its parts is, perhaps, unsurpassed by any engineering work of modern times.

His designs of the East River Bridge, the plans of which he had thoroughly matured, and which have withstood the test of the severest criticism at the hands of the ablest engineering talent of the country, are left as the last, and perhaps the greatest, monument of his engineering skill in coping with physical obstacles that to other less bold and comprehensive minds would have proved insurmountable. In the crypt of St. Paul's Cathedral is a simple slab that marks the tomb of its great designer, Sir Christopher Wren. Upon the slab are inscribed, in effect, these words: "If you would seek his monument, look around you." Thus it is with John A. Roebling; his works are an imperishable monument to his memory—*Engineering and Mining Journal.*

The Great Eastern.—When the eminent engineer, Brunel, built the Great Eastern, he expected to begin a new era in commerce. He supposed his vessel would carry freight and passengers cheaper and more expeditiously and comfortably than other vessels, and that he should work a revolution in shipbuilding and trade. Her first voyage to New York was a failure. She seemed to be an utter failure, and good for nothing. Poor Brunel died of chagrin and disappointment.—*Exchange.*

This is a specimen of the information given to the public about this wonderful ship, by commercial newspapers. Brunel conceived the idea of the Great Eastern, and arranged her double propelling power, but he did not build her, nor did he, in a naval architectural sense, design her. This was Scott Russell's work. That she will carry freight 100 per cent more cheaply than smaller vessels, when fully loaded, is not questioned by experts, and has in fact been demonstrated by the results of other ships of different sizes. The Great Eastern will hold eight times the freight and encounter only four times the resistance, at a given speed, of a vessel of half her length, breadth and depth. As to carrying passengers more comfortably—she has always demonstrated this, except in one case, when she was so ballasted as to roll abnormally. Any ship can be served so. We have sailed as quietly upon her, in mid ocean, as upon Long Island Sound steamers in average weather, and at a time, too, when the vessels passing the Great Eastern were pitching so much as to cause general sea-sickness. The Great Eastern was never filled nor never run on the route for which she was built. It is not probable that the "Scotia" would pay between Boston and New York, immense as the traffic is. How was the first voyage of the ship to New York a failure? We made that voyage in good average time, taking a long detour ; and no one was seasick, though there were two days of heavy weather. The good-for-nothingness of the Great Eastern has been demonstrated by her laying three cables and uniting two continents—a work that would not have been done without her. Finally, Brunel died before she was launched, and consequently not in consequence of her unprofitable voyages, which were, by the way, the result of bad management. We commend these considerations to the penny-a-liners who periodically pitch into the Great Eastern.

The British Telegraph Bill.—The bill for the purchase of the telegraphic lines throughout Great Britain is a measure of great importance. The Government purpose extending telegraphic communication to the suburbs of all the large towns, to all the second-rate towns having railway stations, and to places in which at present there are neither telegraph nor railway stations. It is contemplated to serve, under the new arrangement, 3,376 places, instead of 1,882 now served by telegraphs and railways, and to have 842 branch offices, instead of the 247 existing at present. There is now one telegraph office to every 13,000 of the population; the Government will have one office to every 6.000 of the population. They propose, likewise, the creation of offices of deposit, every letter-box and every pillar-box being such an office, where messages will be received and sent to the telegraph office to be forwarded to their destination. The wires are to be brought into the money order office in every town and district, thereby bringing the telegraph into the center of a population, instead of its remaining, as it frequently does at present, in the outskirts. And they contemplate extending in many places the number of hours during which the telegraph will be accessible to the public. It is proposed also to have one uniform tariff of 1s. for 20 words. The basis of the agreement entered into, under an act passed last year, for the transfer of the lines to the Government, was that a sum amounting to twenty years' purchase of the net profits of the various telegraph companies up the 30th of June of last year should be paid to the proprietors of those undertakings. On this basis the amount to be paid to the companies is over $28,500,000 gold, but other expenses will swell the total cost to $33,500,000. It is expected that the lines will yield a gross revenue close upon $3,500,000, and the expenditure will be nearly $2,000,000, showing about $1,500,000 net profit—enough to pay the interest upon the purchase money and leave a surplus of fully $250,000. The number of inland messages for the year ending last December was 6,000,000, upon which number it is reckoned there will be an increase for the first year of at least 2,500,000. Much of this increase is expected to result from bringing the telegraph nearer the center of the population; experience, both on the continent and in England, having shown that wherever telegraph facilities are by this means placed within easy reach of the people, a large increase on the number of messages is certain to follow. It is noteworthy that, contrary to the opinion of some of the most experienced engineers, the Government, in the estimates, have calculated the life of a cable at fifteen years, and have therefore provided for replacing all the cables at the end of that time.—*Tribune.*

The Darien Canal—An Old Project.—The project of uniting the two oceans by a cut across the Isthmus of Darien, is not a new or a modern one. In 1528 a route for a canal was examined by two Flemish engineers, by the orders of Philip II of Spain, but finding insuperable difficulties, the project was abandoned. In England the project was revived in the latter part of the seventeenth century. In 1826, Domingo Lopez, of New Granada, explored a route for a canal 44 miles in length, between Panama and Portobello. Another survey was made in 1827, under the orders of General Bolivar, by two English engineers, Lloyd and Falmark, who concluded their labors in 1829. The only result of their labors was proving the possibility of either a canal or railroad between Panama and Chagres. In 1843, the French government sent out MM. Garella and Courtines to make explorations. They reported in favor of a canal passing under the dividing ridge of the Ahogayegua by a tunnel 125 feet high from water level, and 17,390 feet long.

Napoleon and the Engineers.—The Emperor Napoleon in his early days was an enthusiastic student of engineering science and an engineer of no mean acquirements; and since his elevation to the throne has shown himself constantly the friend, patron and promoter of all ingenious inventions, and especially of all enterprises embodying the science of construction in public ways and works of all kinds. It is no mere empty compliment, then, that has been offered him by the London Institution of Civil Engineers in electing him an honorary member of that body; and the cordial reception which the Emperor gave the Committee who bore to him official information of it, meant, doubtless, more of genuine pleasure and cordiality than could be found in most international forms of courtesy.—*Y. Y. Times.*

Morton's Ejector-Condenser.—This novel appliance to the steam engine (described and illustrated in Van Nostrand's Magazine, No. 3, p. 225), is making rapid and extensive progress amongst engineers, mine owners, and others. Orders for the condenser and for licenses to manufacture it are being received from all parts of the United Kingdom. No fewer than four condensers were sent off last week to meet as many orders. One has lately been applied to a pumping engine at a colliery belonging to Messrs. Wilsons & Co., of Summerlee Ironworks, and the consumption of coal in six hours was immediately reduced from 56 cwt. to 33 cwt. A more striking instance of economy of fuel effected by using a Morton condenser is that afforded by an engine to which the condenser was applied, near Dalry, in Ayrshire. The consumption of fuel was reduced one-half. So satisfied is the manager of the works (Messrs. Merry and Cunninghame's) with the work done by this condenser, that it is intended to apply the apparatus to several other engines. It has been applied to a Clyde-built screw steamer, lately purchased for the Pontifical Marine, and Messrs. Day & Co., Southampton, have just built a splendid steam yacht, to whose engines it has been applied. In this instance the condenser has been constructed of finely polished gun-metal. —*Engineering.*

Welded Boilers.—A contract was recently let to a Belgian firm for the making of twenty boilers thirteen feet long and three and a half in diameter—the whole to be of half-inch plates, and to be *welded* throughout. No English firm would take the contract.—*Exchange.*

It would be interesting to know whether these boilers are to be welded by Bertram's gas welding process or some modification of it. We can hardly imagine how a perfect job can be made otherwise. We have seen at Woolwich a complex boiler completely and soundly welded by this process.

Mr. Isherwood and General Grant.—Speaking of the President's nomination of chief engineer James W. King to be chief of the Bureau of Steam Engineering, "in place of Isherwood, whom I desire removed," the Engineer says: "We are sorry that Mr. Isherwood has been removed. He was the right man in the right place as far as England was concerned."

Shipping of Liverpool.—The quantity of shipping for sale in the port of Liverpool now amounts to the enormous aggregate of 124,788 tons, thus classified:—Colonial built sailing ships, 39,510 tons; British built ditto, wood, 18,464 tons; ditto iron, 5,266 tons; foreign built, sailing ships, 10,943 tons; new sailing ships, iron and composite, 4,590 tons; screw steamers, 38,180 tons; paddle steamers. 7,835 tons.

Marine Engines.—Messrs. Maudslay, Sons and Field, are completing three pairs of 800-horse power engines for foreign governments. Messrs. John Penn and Son are actively engaged upon the 1200-horse power engines of the Sultan—copies in every respect of the engines of the Hercules. The great crank shaft was forged by Messrs. Rigby and Beardmore, of the Parkhead Forge, Glasgow. It has turned out, in the lathe, as sound a forging as any ever made. Its weight, in the rough, was nearly 35 tons.

Boiler Explosions.—No one doubts that a series of comprehensive experiments conducted by our most competent experts, and costing say $100,000, would develop the causes and remedies for these disasters; yet boiler owners go on blowing up millions of money—not to speak of lives—every year, without spending a cent or making a movement towards a radical cure. So long as the causes of explosions cannot be proved and demonstrated to be simple and accessible, rather than mysterious and remote, so long will there be excuses for mal-construction and mal-practice.

Aerial Navigation.—Upon the heels of the meeting of the British Æronautical Society, which developed little but hopes based upon failures, we have news from California that the great problem is solved. Let us hope so. At the same time, it is difficult to see, with the light we now have, how all the talent, patience and money expended in this direction in England, can have so utterly missed the great possibilities upon which the California inventor has so easily seized.

Ocean Time of the "Dauntless."—The American yacht "Dauntless," Vice Commodore James G. Bennett, jun., recently made the run, from New York to Queenstown, in 12 days 17 hours 6 min. 12 sec., and beating the time of the "Henrietta" in her famous ocean race with the "Fleetwing" and "Vesta." The "Dauntless" experienced heavy weather the entire voyage.

American Running Gear Abroad.—An English firm of coachbuilders announce that they are prepared to build light carriages on wheels imported from America. Now that this innovation has been made it is just possible that the principle of light wheels will be applied to the construction of carts and wagons used in agricultural districts.

Duty of Cornish Engines in England.—Eighteen Cornish engines were reported in April. These consumed 1,468 tons of coal, and lifted 11,700,000 tons of water ten fathoms high. Average duty, 53,700,000 lbs., lifted one foot high by the consumption of 112 lbs. of coal. Seven engines exceeded the average duty.

Neutralizing Miasmatic Gases.—The plan of neutralizing the effects of marshy extralations tried in the fens near Rochefort, and in Holland, with success, is about to be introduced into Lincolnshire. It consists in the cultivation of the sunflower on a large scale.

Large Pumping Engine.—The "Scientific American" states that the third pumping engine for the Brooklyn Waterworks, now being built, will be the largest and most powerful pumping engine in the world, with the exception of one in Cincinnati.

ENGINEERING MAGAZINE.

No. X.—OCTOBER, 1869.—Vol. I.

MODERN MECHANICAL SCIENCE.

From the inaugural address of C. W. Siemens, F. R. S., before Section G (Mechanical Science Section) of the British Association, August 19, 1869.

In prefacing our proceedings with a few remarks on the leading subjects of the day of special interest to our section, I can scarcely pass over the somewhat hackneyed question of technical education.

Technical Education.—The great international exhibitions proved, that although England still holds her ground as the leading manufacturing country, the nations of the Continent have made great strides to dispute her pre-eminence in several branches, a result which is generally ascribed to their superior system of technical education. Those desirous of obtaining a clear insight into that system, and the vast scale upon which it is being carried out under Government supervision, cannot do better than read Mr. John Scott Russell's very able volume on this subject, and they will, no doubt, agree with the author in the necessity of energetic steps being taken in this country to promote the work of universal education. Although I, for one, think that objection may fairly be made against the plan of merely imitating the example of our neighbors.

The polytechnic schools of the Continent, not satisfied to impart to the technical student a good knowledge of mathematics and of natural sciences, pretend, also, to superadd the practical information necessary to constitute them engineers or manufacturers.

This practical information is conveyed to them by professors, lacking themselves practical experience, and tends to engender in the students a dogmatical conceit, which is likely to stand in the way of originality in the adaptation of new means to new ends in their future career. On this account, I should prefer to see a sound "fundamental" education, comprising mathematics, dynamics, chemistry, geology and physical science, with a sketch only of the technical arts, followed up by professional training, such as can only be obtained in the workshop, the office or the field.

Patents.—Closely allied to the question of education is that of the system of Letters Patent. A patent is, according to modern views, a contract between the Commonwealth and an individual who has discovered a method, peculiar to himself, of accomplishing a result of general utility. The State, being interested to secure the information, and to induce the inventor to put his invention into practice, grants him the exclusive right of practising it, or of authorizing others to do so, for a limited number of years, in consideration of his making a full and sufficient description of the same. Unfortunately, this simple and equitable theory of the patent system is very imperfectly carried out, and is beset with various objectionable practices, which render a patent sometimes an impediment to, rather than a furtherance of applied science, and sometimes involves the author of an invention in endless legal contentions and disaster, instead of procuring for him the intended reward. These evils are so great and palpable, that many persons, including men of undoubted sincerity and sound judgment on most subjects, advocate the entire abolition of the Patent Laws. They argue that the desire to publish the results of our mental labor suffices to ensure to the Commonwealth the possession of all new discoveries or inventions, and that justice might be done to meritorious inventors by giving them national rewards.

This argument may hold good as regards a scientific discovery, where the labor bestowed is purely mental, and carries with it the pleasurable excitement peculiar to the exercise and advancement of science on the part of the devotee ; but a practical invention has to be regarded as the result of a first conception, elaborated by experiments and their application to existing processes in the face of practical difficulties, of prejudice, and of various discouragements, involving also great expenditure of time and money, which no man can well afford to give away, nor can men of merit be expected to advocate their cause before the national tribunal of rewards, where at best only very narrow and imperfect views of the ultimate importance of a new invention would be taken, not to speak of the favoritism to which the doors would be thrown open. Practical men would undoubtedly prefer either to exercise their inventions in secret, where that is possible, or to desist from following up their ideas to the point of their practical realization. If we review the progress of the technical arts of our time, we may trace important practical inventions almost without exception to the Patent Office. In cases where the inventor of a machine or process, happened to belong to a nation without an efficient patent law, we find that he readily transferred the scene of his activity to the country offering him the greatest encouragement, there to swell the ranks of intelligent workers. Whether we look upon the powerful appliances that fashion shapeless masses of iron and steel into railway wheels or axles, or into the more delicate parts of machinery ; whether we look upon the complex machinery in our cotton factories, our dye works and paper mills, or into a Birmingham manufactory, where steel pens, buttons, pens, buckles, screws, pencil-cases, and other objects of general utility are produced by carefully elaborated machinery, at an extremely low cost ; or whether we look upon our agricultural machinery, by which England is enabled to compete, without protection, against the Russian or Danubian agriculturist, with cheap labor and cheap land to back him, in nearly all cases we find that the machine has been designed and elaborated in its details by a patentee who did not rest satisfied till he had persuaded the manufacturers to adopt the same, and removed all their real or imaginary objections to the innovation. We also find that the knowledge of its construction reaches the public directly or indirectly through the Patent Office, thus enlarging the basis for further inventive progress.

The greatest illustration of the beneficial working of the patent laws, was supplied, in my opinion, by James Watt, when, just about 100 years ago, he patented his invention of a hot working cylinder and separate steam engine condenser. After years of contest against those adverse circumstances that beset every important innovation, James Watt, with failing health and scanty means, was only upheld in his struggle by the deep conviction of the ultimate triumph of his cause. This conviction gave him confidence to enlist the co-operation of a second capitalist, after the first had failed him, and of asking for an extension of his declining patent.

Without this opportune help Watt could not have succeeded to mature his invention ; he would, in all probability, have relapsed into the mere instrument maker, with broken health and broken heart, and the invention of the steam engine would not only have been retarded for a generation or two, but its final progress would have been based probably upon the coarser conceptions of Papin, Savory and Newcomen.

It can easily be shown that the perfect conception of the physical nature of steam, which dwelt like a Heaven-born inspiration in Watt's mind, was neither understood by his contemporanies nor by his followers, up to very recent times ; nor can it be gathered from Watt's very imperfect specification. James Watt was not satisfied to exclude the condensing water from his working cylinder, and to surround the same by non-conducting substances, but he placed between the cylinder and the non-conducting envelope, a source of heat in the form of a steam jacket, filled with steam at a pressure somewhat superior to that of the working steam. His successors have not only discarded the steam jacket, and even condemned it on the superficial plea that the jacket presented a larger and hotter surface for loss by radiation than the cylinder, but expansive working was actually rejected by some of them on the ground that no practical advantage could be obtained by it. The modern engine, notwithstanding our perfected means of construction, had in fact degenerated in many instances into a simple steam-meter, constructed apparently with a view of emptying the boiler in the shortest possible space of time.

It is only during the last twenty years that the subtile action of saturated steam in condensing upon the sides of the cylinder when under pressure, and of evaporating when the pressure is relieved toward the end of each stroke, has been again recognized and insisted upon by Lechatelier and others, who have shown the necessity of a slightly super-heated cylinder in order to realize the expansive force of steam.

The result has been a reduction in the consumption of fuel in our best marine engines from 6 to 8 to below 3 lbs. per gross indicated horse power.

Would it be safe in view of such facts as these to discard the patent laws which, as I have endeavored to show, lay at the very foundation of our modern progress, without making at all events a serious effort to remedy those evils, which, it is admitted on all hands, now adhere to them? These evils need for the most part no special legislation, but can be traced to the imperfect manner in which the existing patent laws are carried into effect.

It is a hopeful circumstance that during the next session of Parliament, the whole question of the patent laws is likely to be inquired into by a special committee, who, it is to be hoped, will act decidedly in the general interest, without being influenced by special or professional claims. They will have it in their power to render the Patent Office an educational institution of the highest order.

The Great Works of the Year.—In viewing the latest achievements of engineering science, two works strike the imagination chiefly by their exceeding magnitude, and by the influence they are likely to exercise upon the traffic of the world. The first of these is the great Pacific Railway, which, in passing through vast regions hitherto inaccessible to civilized man, and over formidable mountain chains, joins California with the Atlantic States of the great American republic. The second is the Suez shipping canal, which, notwithstanding adverse prognostications and serious difficulties, will be opened very shortly to the commerce of the world. These works must greatly extend the range of commercial enterprise in the North Pacific and the Indian Seas. The new waterway to India, will, owing to the difficult navigation of the Red Sea, be in effect only available for ships propelled by steam, and will give a stimulus to that branch of engineering.

Telegraphs.—Telegraph communication with America has been rendered more secure against interruption by the successful submersion of the French Transatlantic Cable. On the other hand, telegraphic communication with India still remains in a very unsatisfactory condition, owing to imperfect lines and divided administration.

To supply a remedy for this public evil, the Indo-European Telegraph Company will shortly open its special lines for Indian correspondence. In Northern Russia, the construction of a land line is far advanced to connect St. Petersburg with the mouth of the Amour river, on completion of which only a submarine link between the Amour and San Francisco will be wanting to complete the telegraphic girdle round the earth.

With these great highways of speech once established, a network of submarine and aërial wires will soon follow, to bind all inhabited portions of our globe together into a closer community of interests, which, if followed up by steam communication by land and by sea, will open out a great and meritorious field for the activity of the civil and mechanical engineer.

Railways.—But while great works have to be carried out in distant parts, still more remains to be accomplished nearer home. The railway of to-day has not only taken the place of high roads and canals, for the transmission of goods and passengers between our great centers of industry and population, but is already superseding by-roads leading to places of inferior importance; it competes with the mule in carrying minerals over mountain passes, and with the omnibuses in our great cities. If a river cannot be spanned by a bridge without hindering navigation, a tunnel is forthwith in contemplation; or, if that should not be practicable, the transit of trains is yet accomplished by the establishment of a large steam ferry.

It is one of the questions of the day to decide by which plan the British Channel should be crossed, to relieve the unfortunate traveler to the Continent of the exceeding discomfort and delay inseparable from the existing most imperfect arrangements. Considering that this question has now been taken up by some of our leading engineers, and is also entertained by the two interested

Governments, we may look forward to its speedy and satisfactory solution.

So long as the attention of railway engineers was confined to the construction of main lines, it was necessary for them to provide for a heavy traffic and high speeds, and these desiderata are best met by a level, permanent way, by easy curves, and heavy rails of the strongest possible materials, namely, cast steel, but in extending the system to the corners of the earth, cheapness of construction and maintenance, for a moderate speed, and a moderate amount of traffic, become a matter of necessity.

Instead of plunging through hill and mountain, and of crossing and recrossing rivers by a series of monumental works, the modern railway passes in zigzag up the steep incline, and conforms to the windings of the narrow gorge; it can only be worked by light rolling stock of flexible construction, furnished with increased power of adhesion and great brake power. Yet, by the aid of the electric telegraph, in regulating the progress of each train, the number of trains may be so increased as to produce, nevertheless, a large aggregate of traffic, and it is held by some that our trunk lines even would be worked more advantageously by light rolling stock.

The brake power on several of the French and Spanish railways has been greatly increased by an ingenious arrangement, conceived by M. Lechatelier, of applying what has been termed "contre vapeur" to the engine, converting it for the time being into a pump forcing steam and water into the boiler.

Warfare.—While the extension of communication occupies the attention of perhaps the greater number of our engineers, others are engaged upon weapons of offensive and defensive warfare. We have scarcely recovered our wonder at the terrific destruction dealt by the Armstrong gun, the Whitworth bolt, or the steel barrel consolidated under Krupp's gigantic steam hammer, when we hear of a shield of such solidity and toughness, as to bid defiance to them all. A larger gun, or a hard bolt by Palliser or Gruson, is the successful answer to this challenge, when again defensive plating, of greater tenacity to absorb the power residing in the shot, or of such imposing weight and hardness combined as to resist the projectile absolutely (causing it to be broken up by the force residing within itself), is brought forward.

The ram of war with heavy iron sides, which a few years since was thought the most formidable, as it certainly was the most costly weapon ever devised, is already being superseded by vessels of the Captain type, as designed by Captain Coles, and ably carried out by Laird Brothers, with turrets (armed with guns of gigantic power) that resist the heaviest firing, both on account of their extraordinary thickness, and of the angular direction in which the shot is likely to strike.

By an ingenious device Captain Moncrieff lowers his gun upon its rocking carriage after firing, and thereby does away with embrasures (the weak place in protecting works), while at the same time he gains the advantage of reloading his gun in comparative safety.

It is presumed that in thus raising formidable engines of offensive and defensive warfare, the civilized nations of the earth will pause before putting them into earnest operation, but if they should do so, it is consolatory to think that they could not work them for long without effecting the total exhaustion of their treasuries, already drained to the utmost in their construction.

Iron and Steel.—While science and mechanical skill combine to produce these wondrous results, the germs of further and still greater achievements are matured in our mechanical workshops, in our forges, and in a metallurgical smelting works; it is there that the materials of construction are prepared, refined and put into such forms as to render greater and still greater ends attainable. Here a great revolution of our constructive art has been prepared by the production, in large quantities, and at moderate cost, of a material of more than twice the strength of iron, which, instead of being fibrous, has its full strength in every direction, and which can be modulated to every degree of ductility, approaching the hardness of the diamond on the one hand, and the proverbial toughness of leather on the other. To call this material cast steel seems to attribute to it brittleness and uncertainty of temper, which, however, are by no means its necessary characteristics. This new material, as prepared for constructive purposes, may, indeed, be both hard and tough, as is illustrated by the hard steel rope that has so materially contributed to the practical success of steam ploughing. Machinery steel has gradually come into use since about 1850, when Krupp, of Essen, commenced to supply large ingots that were shaped into railway tyres, axles, cannon, &c., by melting steel in furnaces containing hundreds of melting crucibles.

The Bessemer process, in dispensing with the process of puddling, and in utilizing the carbon contained in the pig iron to effect the fusion of the final metal, has given a vast extension to the application of cast steel for railway bars, tyres, boiler plates, &c.

The process is limited, however, in its application to superior brands of pig iron, containing much carbon, and no sulphur or phosphorus, which latter impurities are so destructive to the quality of steel. The puddling process has still to be resorted to, to purify these inferior pig irons, which constitute the bulk of our productions, and the puddled iron cannot be brought to the condition of cast steel except through the probess of fusion. This is accomplished successfully in masses of from 3 to 5 tons on the open bed of a regenerative gas furnace, at the Landore Siemens Steel Works, and at other places. At the same works cast steel is also produced, to a limited extent as yet, from iron ore, which, being operated upon in large masses, is reduced to the metallic state, and liquified by the aid of a certain proportion of pig metal. The regenerative gas furnace, the application of which, to glass houses, to forges, &c., has made considerable progress, is unquestionably well suited for this operation, because it combines an intensity of heat, limited only by the point of fusion of the most refractory material, with extreme mildness of draught and chemical neutrality of flame.

These and other processes of recent origin, tend toward the production, at a comparatively cheap rate, of a very high class material, that must shortly supersede iron for almost all structural purposes. As yet engineers hesitate, and very properly so, to construct their bridges, their vessels, and their rolling stock, of the material produced by these processes, because no exhaustive experiments have been published as yet, fixing the limit to which they may safely be loaded in extension, in compression and in torison, and because they have as yet no sufficient information regarding the tests by which their quality can best be ascertained. This great want is in a fair way of being supplied by the experimental researches that have been carried on for some time at Her Majesty's dockyards at Woolwich, under a committee appointed for that purpose by the Institution of Civil Engineers. In the meantime excellent service has been rendered by Mr. Kirkaldy, in giving us, in a perfectly reliable manner, the resisting power and ductility of any sample of material which we wish to submit to his tests. The results of Mr. Whitworth's experiments, tending to render the hammer and the rolls obsolete, by forcing cast steel, while in a semi-fluid state, into strong iron moulds by hydraulic pressure, are looked upon with great interest. But assuming that the new building material has been reduced to the utmost degree of uniformity and cheapness, and that its limits of strength are fully ascertained, there remains still the task for the civil and mechanical engineer to prepare designs suitable for the development of its peculiar qualities. If in constructing a girder, for example, a design were to be adopted that had been worked out for iron, and if all the scantlings were simply reduced in the inverse proportion of the absolute and relative strength of the new material as compared with iron, such a girder would assuredly collapse when the test weight was applied, for the simple reason that the reduced sectional area of each part, in proportion to its length, would be insufficient to give stiffness. You might as well almost take a design for a wooden structure, and carry it out in iron, by simply reducing the section of each part. The advantages of using the stronger material become most apparent, if applied, for instance, to large bridges, where the principal strain upon each part is produced by the weight of the structure itself; for supposing that the new material can be safely weighted to double the bearing strain of iron, and that the weight of the structure were reduced by one-half accordingly, there would still remain a large excess of available strength, in consequence of the reduced total weight, and this would justify a further reduction of the amount of the material employed. In constructing works in foreign parts, the reduced cost of carriage furnishes also a powerful argument in favor of the stronger material, although its price per ton might largely exceed that of iron.

Coal and Power.—The inquiries of the Royal Commission into the extent and management of our coalfields, appear to be reassuring as regards the danger of their becoming soon exhausted; nevertheless, the importance of economizing these precious deposits in the production of steam power in metallurgical operations, and in domestic use, can hardly be overestimated. The calorific power residing in a pound of coal of a given analysis, can now be accurately expressed in units of heat, which again are represented by equivalent units of force, or of chemical action; therefore, if we ascertain the consumption of coal of a steam engine, or of a furnace employed in metallurgical operations, we are able to tell by the light of physical science, what proportion of the heat of combustion is utilized, and what proportion is lost. Having arrived at this point, we can also trace the channels through which loss takes place, and in diminishing these by judicious improvement, we shall more and more approach those standards of ultimate perfection which we can never reach, but which we should nevertheless keep steadfastly before our eyes. Thus a pound of ordinary coal is capable of producing 12,000 Fahrenheit units of heat, which equal 9,264,000 foot-pounds or units of force, whereas the very best performances of our pumping engines do not exceed the limit of 1,000,000 foot-pounds of force per pound of coal. In like manner 1 lb. of coal should be capable of heating 33 lbs. of iron to the welding point of say 3000° Fahr., whereas in an ordinary furnace not 2 lbs. of iron are so heated with 1 lb. of coal. These figures serve to show the great field for further improvement that lays yet before us.

Refrigeration.—Although heat may be said to be the moving principle by which all things in nature are accomplished, an excess of it is not only hurtful to some of our processes, such as brewing, and destructive to our nutriments, but to those living in hot climates, or sitting in crowded rooms, an excess of temperature is fully as great a source of discomfort as excessive cold can be. Why, then, may I ask, should we not resort to refrigeration in summer, as well as to calorification in winter, if it can be shown that the one can be done at nearly the same cost as the other? So long as we rely for refrigeration upon our ice cellars, or upon importation of ice from distant parts, we shall have to look upon refrigeration as a costly luxury only, but by the use of properly constructed machines it will be possible, I believe, to produce refrigeration at an extremely moderate expenditure of fuel and labor. A machine has already been constructed capable of producing 9 lbs. of ice or its equivalent for 1 lb. of coal, whereas the equivalent values of positive heat developed in the combustion of 1 lb. of coal, and of negative heat residing in 1 lb. of ice, is about as 12,000 to 170, or as 1 to 70. This result already justifies the employment of refrigerating machines upon a large scale, but it is hard to say what practical results may yet be reached with an improved machine on strictly dynamical principles, because such a machine seems not tied in its results to any definite limits. In changing, for instance, a pound of water from the liquid into the gaseous state, a given number of units of heat are required, that may be produced by combustion of coal or by the expenditure of force, but in changing the same pound of water into ice, heat is not lost but gained in the operation, which heat must be traceable to another part of the machine, either as sensible heat or as developed force. It would lead me too far to enter at present into particulars on this question, which is one not without interest for the physicist and the mechanical engineer.

SEA COAST DEFENSE.

THE MONCRIEFF SYSTEM OF WORKING ARTILLERY.

From a paper by Captain Moncrieff, before the Royal Institution of Great Britain.

Until the time of the Crimean war very little and very slow progress had been made in artillery. Canon were manufactured on nearly the same models, and of the same materials, that had been used for 300 years. Before that time cast-iron was not in use, but the forged or bronze guns, although in some cases large, were not what is now considered powerful, and the penetration of their shot was not sufficient to pass through a parapet of earth that is now pierced even by light rifled artillery. The conditions, therefore, under which artillery was worked, and the means provided for protection against its fire, remained much the same as they were in the time of Vauban. Several events during the Crimean campaign confirmed an impression that has always been more or less entertained—that an increase in the power of individual guns produced greater results than could be obtained by a much greater weight of metal, distributed among a larger number of small pieces of artillery. It is not too much to say that the development of this art has, since 1855, changed the character of war both on land and water. It has established completely the superiority of a few large pieces over a much greater weight of metal in smaller guns. It has given artillery of all classes a range, penetration, and an accuracy of *Fire*, which throw into the shade the greatest results that had been previously obtained. It has also stimulated the advocates of cast-iron smooth bores to produce guns that might rival the rifled artillery; and yet it is by no means probable that the limit of power, either of large smooth-bores or rifled guns, has been arrived at. When it became apparent that mighty results were to be obtained from improved artillery, a great deal of engineering talent was directed to the subject. Comparatively new appliances, such as the steam-hammer, and new methods of working steel, were called to aid in the construction of the new and powerful guns. So much interest, indeed, was taken in the subject, and so much attention absorbed by it, that the conditions which these improvements in artillery themselves imported with them ran some danger of being neglected. The power of artillery became so great that the ordinary provisions for protection against its fire were rendered useless. Forts that were considered strong twenty years ago would crumble under the shock of modern projectiles, and in some cases would be even too weak to support the guns while they were fired. That service which the new artillery affected most palpable was the Navy, and the Navy accordingly took the initiative in introducing means calculated to resist the penetration of the new and terrible projectiles. Every one is more or less conversant with the process that has been going on of covering ships' sides with iron, which has increased in thickness till it really looks as if the process at last would only be limited by a ship's power of flotation. Warships, however, not only protect their sides against shot, but they also carry the heaviest artillery on their decks. This fact could not be overlooked by those who had to construct coast defenses, as well as other works against which modern heavy artillery might be used.

I shall not enter into details regarding the successive steps which were taken in England in this direction, as I understand Colonel Jervoise has already done so in this Institution. It is enough to state that great engineering skill has been exercised, and unwearied efforts have been made to meet the new conditions. That skill and these efforts have, with the experiments at Shoeburyness, given us defensive iron structures which are marvels of strength and ingenuity. Unfortunately they are also marvels of costliness; and there is room to hope that their use will therefore be generally confined to such positions on *land* as can only be protected by such iron structures. This hope is founded on another system, with which my name is connected, and which I am here to explain. Before doing so I shall point out the dilemma which left military engineers no alternative, and which compelled them to give up in succession the use of earth, concrete, granite, etc., and at last to resort to the most expensive, but the strongest, material—*iron.*

There are two considerations always to be taken into account in providing the means of using artillery: the one is to place the gun so as to be most formidable to the enemy, and the other is to place it at the same time under as much cover as possible, so that it is not liable to be disabled, nor are the men serving it liable to be destroyed by hostile fire. These two conditions interfere with one another; that is to say, whatever has hitherto been gained in one direction has been lost in the other. Guns, *en barbette*, lack protection; guns in embrasures or in casemates sacrifice, on the other hand, free lateral range, and it is more difficult in their case to see the enemy, and therefore to lay the guns in action. The difficulty that presented itself with the introduction of late improvements in artillery was simply that the increased precision and range, coupled with great improvements in the manufacture of large shells and also in small arms, rendered barbette batteries too exposed to be relied on. At the same time the tremendous penetration and precision of the new artillery rendered the ordinary parapet and embrasures useless. What was to be done under these circumstances? Protection from direct fire must be got at any price. The first impulse would be to thicken the parapet. This could not, however, be done, as the necessary angle in the cheeks of the embrasures required for training the guns opens up a wider aperture, in direct proportion to the thickness of the parapet, making the *maximum* thickness in practice 30 ft. But shot have been known to penetrate more than 30 ft. into the earth; and the most important part of the parapet, viz: that near the guns, must always be thin and weak, whatever may be the thickness of the rest. Shells, striking this part, would just meet sufficient resistance to burst them, and would make havoc among the men. Next, granite masonry was thought of; but it proved in some respects worse than earth, and was found practically bad; there was no alternative but to go to iron. This conclusion was reluctantly arrived at, and reluctantly it was acted on.

The decisions of committees which investigated all the bearings of the question, the opinions of professional men and the experiences of the American war, all coincided, and accordingly our important coast-works were designed to receive *iron* shields, casemates and cupolas. Vital positions in England, such as dockyards and arsenals, must be fortified. It would be false economy, indeed, to use any method of fortification that experience has proved to be insufficient. *No savings* could justify the erection of works that might prove at once the tomb of their defenders and perhaps of the nation's honor. Therefore the only proper decision was to take that means to meet the difficulty which was at the time considered best and safest. Expense was properly a consideration very secondary in importance to efficiency.

I shall now endeavor to point out the difficulty of the task which lay before the engineer, even after the decision in favor of iron, from the extraordinary advances, already spoken of, in artillery. There is only one morsel of comfort left for those who have to provide for the requirements of defense, viz: that a form of artillery fire of a very galling nature remains exactly as before, and indeed is not much better, than it was in the time of Queen Elizabeth. What is alluded to is vertical or mortar fire. There is some consolation, too, in the reflection that the cause of this fire not being much improved is one to a great extent likely to be lasting. Rifled mortars would no doubt lessen deflection to right or left; but as long as gunpowder is affected in strength by the slightest atmospheric or other influence, and still more certainly as long as a slight error in elevation at long ranges will make a large error on the plane of fire, the comparative inaccuracy of vertical fire must continue. To show how little can be done in this way compared with the admirable precision and accuracy of direct fire, I may state that 100 rounds were fired one day last season at Shoeburyness at 800 yards range, with a 13-in. mortar, at the row of experimental casemates, which cover a good deal of ground. The mortar was laid with spirit-levels and all the appliances of the school of gunnery, and yet the 100 rounds were expended without a single hit. If such is the case with a steady platform and under such exceptionably favorable circumstances, it can easily be seen how uncertain in its effects would practice be from mortar-boats, which move with every wave, if directed at an equally small object. During the eleven months' siege of Sebastopol the French had 242 mortars engaged, which were themselves exposed to vertical fire, and yet not one of these mortars was disabled. It is indeed a strange contrast—that while direct fire is getting more powerful, more accurate and more destructive every year, vertical fire remains much as it was, and can only be relied on to hit a large object, such as a fort, a town, or anything that covers a good deal of ground. Notwithstanding this, it would be a great mistake to despise it as a powerful and galling means of attack.

To return to the difficulties of meeting direct fire in coast defense. It must be borne in mind that the batteries intended to engage ships are obliged to meet an enemy who can move his position to that quarter where he is least exposed, who can continue in motion while he is conducting his attack, and who can seek out the most vulnerable face of the land-work to operate upon. In constructing such batteries it is first of all necessary to make them of sufficient strength to resist the guns of ships which are the most powerful that can be made. It is next required that these batteries should be constructed in such a manner that they can direct their fire with rapidity and precision in any direction in which the ships can take up their position. And lastly, it is required that they should mount guns of sufficient weight and power to be formidable to the heaviest iron-clads.

In former times guns *en barbette* were preferred for this purpose, because they met the two first requirements alluded to; that is to say, that from not being confined by embrasures or ports, they were able freely to follow their floating enemy, whatever position he might take up; naval fire at that time being neither so correct nor so formidable as to make such batteries unserviceable. The case, however, is now completely changed; for not only have guns been improved, but ammunition also, and heavy shells are most destructive. Rear-Admiral Porter, of the United States Navy, in a report on coast defenses, says: "Such guns, *standing so high up*, are just the objects that naval gunners would delight to explode their shrapnel against, and, from my experience in naval gunnery, the third shell would kill every man at the gun." Von Scheliha, in his treatise on coast defenses, "Guns mounted *en barbette* may always be silenced by an iron-clad." This form of battery, therefore, is disposed of. We shall now examine the difficulties connected with the other alternatives. Common masonry batteries have been condemned as worse than useless, as they would only make the ship's fire more destructive than if directed against guns *en barbette.*

Next comes the expensive alternative which has been adopted, viz: iron shields, casemates and turrets. It is most interesting to examine how far this system of iron, the last alternative left, meets the three requirements of coast defense alluded to, and to see what very great difficulties had to be encountered in applying it.

The three requirements are thus recapitulated:—1st. Strength of the battery to resist naval fire, and give sufficient protection to the men. 2d. Power of figthing the guns with accuracy and effect, of following the enemy with ease as he moves, of being able to face him on any side from which he approaches. 3d. Power of using the most formidable guns to advantage.

The first difficulty was to decide the matter of strength. Now guns are becoming more and more weighty and powerful every day, and therefore the strength required to resist them is an unknown quantity. An iron casemate of the present proposed strength costs, according to official returns, with all the battery adjuncts except the gun and carriage, about £5,000 or £6,000 for each gun. A 2-gun turret, about £25,000 or £30,000.* If guns of 50 tons are introduced in ships, as is proposed, these defenses are at once quite inefficient, and it is not known how strong or how expensive should be the iron works to replace them. Such questions must be very embarrassing indeed to those who have to decide these matters. Besides protecting the gun and carriage from the enemy's shot, protection must also be given to the men. This is the most serious of all considerations in coast defense, for the following reasons: The best experience we have regarding naval attacks on land-works is derived from the late American war, in which a great many actions of that kind took place. It would be unwise to ignore this experience, because the increasing power of artillery only gives it more weight. During the whole of that war very few guns were destroyed by the naval fire in earthen batteries. At Fort Wagner, only three guns were totally dismounted, although 2,864 shot and shell were fired into it in 48 hours, and the bomb-proofs were hit 1,200 times. Seventeen siege mortars, several cohorns and thirteen heavy pieces of artillery were incessantly employed. At Fort Fisher the bombardment was opened at the rate of 115 shells per minute, and although the guns were mounted *en barbette*, only two of them were dismounted when the place fell. At Fort Powell a tremendous bombardment from mortar and gunboats (the most accurate firing being from 15-in. mortars) was maintained from 22d of February till 2d of March, and not a single gun was dismounted. The success of the ships over the forts was gained by demolishing the works, and still oftener by making the service of the guns so dangerous that the men could not work them.

Rear-Admiral Porter, U. S. Navy, in his report on coast defense, states: "The new fashioned casemates turned out to be no better than the guns *en barbette.* They were perfect slaughter-houses, and were piled up with dead and wounded. Every shell that went through the port-holes killed and wounded every man in the close casemate. This proved to me most satisfactorily that guns in casemates were no better protected from shells than those *en barbette.*"

With such evidence as this before them, from men who were conversant with all the events of that great war, it was indeed a serious question to decide what was to be done. I myself cannot see how men in an iron casemate are as much exposed as in a barbette battery; but there is no doubt that if the port of the strongest casemate was as large as those referred to by Admiral Porter, it would be open in the same circumstances to the same dangers, as the damage was done by entrance of shell through the port. The protection a casemate would afford from vertical fire in such a case would be but a poor advantage if more correct and more deadly weapons than the mediæval mortar could still search out at times the

* The price of a permanent Moncrieff battery, with magazines, etc., including the extra expense of carriages, is from £1,100 to £1,500 for each gun; an iron shield battery, from £1,800 to £2,000 per gun; an iron casemate battery, from £5,000 to £6,000 per gun; a turret, from £12,000 to £15,000 per gun.

exposed point of a casemate and kill every man inside. The next requirements in a coast battery, viz: to be able to follow an enemy amidst clouds of smoke, and to lay the guns on him with precision and dispatch, formed a more embarrassing difficulty still. On the one hand, the ports must be constructed for muzzle-pivoters to give protection. On the other hand, if they are made so small it is difficult to see through them, to fire correctly and quickly at different elevations and on different sides on a moving enemy. The battery is in the position of a knight, who must either expose his vitals to his enemy's lance or put on an armor that paralyzes his sword arm. There is as much protection in the power of being able to strike as there is in being able to guard. As naval actions are likely to be short and decisive, it must have appeared extremely doubtful whether it was worth purchasing increased safety at the expense of losing the attacking power. The last of the three requirements in coast defense stated was the necessity of using the most powerful canon. This did not present the same difficulty as the other two, because the designers of our defenses had been presented by my friend Captain Coles with the means of mounting the heaviest guns to fire in any required direction. When very large and valuable guns are used, it is not advisable to cramp their action and restrict it to a small area. The turret was therefore preferred to the casemate when lateral range was required; and though apparently very expensive, it was in reality cheaper than casemates, because, although the mounting of guns in this manner cost more, they were enabled to do much more work, and there was thus an economy both of guns and men.

Having thus far endeavored to describe the extraordinary difficulties which the new improvements in artillery inevitably entailed on the engineers, I shall now direct your attention for a short time to the difficulties in which the same improvements involved the artillerymen themselves. These difficulties, though not quite so important as the engineering ones, were very serious indeed, and had not yet been quite overcome. They consisted chiefly in the difficulty of making carriages and platforms strong enough for the new and powerful rifled guns. These pieces burnt enormous charges of powder, and hurled bolts as heavy as an old field piece at 1,000 ft. a second. The recoil of such guns represents a violence of force the like of which man has never had to deal with before. Imaging 12, 18, or 25 tons of compact iron started in an instant into rapid motion with a violence that mocks the blow of a steam-hammer. This force has to be controlled and restrained. It is no wonder then that, when met directly and stopped by friction, as is now done in the ordinary system, the difficulties are enormous. The horizontal strain on the platforms, pivots and racers, is so great that it has not yet been quite successfully met; constant changes and inventions are being made to render this force more harmless.

I hope I have now conveyed to your minds some idea of the embarrassment and difficulties which have fallen upon both the artillery and engineers by the rapid improvement of these formidable engines of war, and of the persistent, able struggle which both have maintained to meet directly the terrible forces with which they have to contend. They have both succeeded to a wonderful extent, but their success is blighted by that curse of the science they practice—the law that up to this time has existed—viz: that what was gained in protection was lost in efficiency, and the converse. Happily, I had the good fortune to conceive and develop an idea which abrogates this law. The very force, the existence of which has been so great a difficulty in the artilley question, has been compelled to perform a service that at once sweeps out of existence a great many of those other difficulties that embarrassed fortification. When two evils co-exist, it is sometimes good policy to make them destroy each other.

I shall now refer shortly to the train of ideas that led me to think of solving this important problem in quite a different manner from that in which it had been attempted, which had led to the adoption of a most expensive class of works. My solution gives a system capable of mounting the heaviest artillery, while it simplifies the vexed question of fortification. It gives protection without the expense of using iron, and free lateral range to the guns without exposure. The system is indeed a simple one; it does not require either brute strength or heavy expenditure for its application; nor does it need mighty forges to weld iron walls to protect our guns and gunners; it only calls to our aid the simplest and most docile forces of nature. Instead of trying to meet force by force, I make my guns bow to the inevitable conditions which science has imposed; and instead of wasting energy, money and skill in attempts to raise a buttress against the new artillery, I employ the hitherto destructive force of recoil to lower the gun below the natural surface of the ground, where it can be loaded and worked in security and in comfort; and at the same time, I have made that destructive force so much my servant that I compel it at my pleasure to raise the gun again into the fighting position whenever it is required. In 1855, while watching the interesting operations before Sebastopol, and endeavoring, as well as I could, to understand the conditions under which the siege artillery was used, I conceived the idea which is now realized. It was then that I saw the value of earth and the importance of simple expedients. It was plain that the weak point of a battery was the embrasure, which formed a mark to fire at, an opening to admit the enemy's shot, and required constant repair even from the effects of its own gun, which in firing injured the revetments of the cheeks. I also came to the conclusion in my own mind that a remedy for some of these defects could be devised. Afterwards I worked at various plans, of which sketches were made, or models; but each design had defects which discovered themselves to me as my experience increased. The real difficulty of the thing arose from the necessity of providing for the enormous strain of the recoil. These early designs, which were sometimes excellent in other respects, broke down at this difficulty, and although some of them no doubt would answer with small guns, they were not calculated to meet the tremendous recoil of large rifled pieces.

At last I hit on a simple principle that would meet this difficulty to advantage—the interposition of a moving fulcrum between the gun and platform. Then I knew that the problem could be solved; and feeling the great importance of the subject, I resolved to devote my efforts to working it out completely. While directing my attention to this simple and then apparently obscure matter, I was, as you may imagine, neither an idle nor disinterested watcher of the progress of artillery. Every step in advance was riveting the certainty in my mind that the system would one day be required, and with this conviction I refused to allow either discouragement or delay to make me desist. I shall now endeavor to explain shortly the system which bears my name, as far as it relates to coast defense.

It consists of three parts: 1st. The mechanical principle of the gun carriages. 2d. The form internal and external of the batteries. 3d. The selection of ground for placing the batteries, and the arrangement for working them to the greatest effect; or, in other words, the *tactics* of defense for positions where the system is employed. The principle on which the carriage is constructed is the first and most important part of the new system, because on it depends the possibility of applying the other parts. This principle may be shortly stated as that of utilizing the force of the recoil in order to lower the whole gun below the level of the crest of the parapet, so that it can be loaded out of sight and out of exposure, while retaining enough of the force above referred to bring the gun up again into the firing or fighting position. This principle belongs to all the carriages; but the forms of these carriages, as well as the method in which this principle is applied, vary in each case. For instance, in siege-guns, where weight is an element of importance, the recoil is not met by counterpoise. With heavy garrison guns, on the other hand, which when once mounted remain permanent in their positions, there is no objection to weight. In that case, therefore, the force of gravity is used to stop the recoil, because it is a force always the same, easily managed and not likely to go wrong; and as these carriages are employed for the most powerful guns, it is a great advantage to have the most simple means of working them.

It has been already mentioned that the principal difficulty arose from the enormous and hitherto destructive force of the recoil of powerful guns; and here I shall point out the manner in which that difficulty is overcome. That part of the carriage which is called the elevator may be spoken of and treated as a lever; this lever has the gun-carriage axle at the end of the power-arm, and the center of gravity of the counter weight at the end of the weight-arm, there being between them a moving fulcrum. When the gun is in firing position, the fulcrum on which this lever rests is almost coincident with the center of gravity of the counter-weight, and when the gun is fired the elevators roll on the platform, and consequently the fulcrum, or point of support, travels away from the end of the weight-arm towards the end of the power-arm; or in other words, it passes from the counterweight towards the gun. Notice the important result of this arrangement. When the gun is fired its axle passes backwards on the upper or flat part of a cycloid. It is free to recoil, and no strain is put upon any part of the structure, because the counter-weight commences its motion at a very low velocity. As the recoil goes on, however, the case changes completely, for the moving fulcrum travels towards the gun, making the weight-arm longer and longer every inch it travels. Thus the resistance to the recoil, least at first, goes on in an increasing progression as the gun descends, and at the end of the recoil it is seized by a self-acting pawl or clutch. The recoil takes place without any jar, without any sudden strain, and its force is retained under the control of the detachment to bring up the gun to the firing position at any moment they may choose to release it. The recoil, moreover, however violent at first, does not put injurious horizontal strain on the platform. In my experiments at Edinburgh with a 32-pounder, I found that so slight was the vibration on the platform caused by firing that the common rails on which the elevators rolled in that experiment, and which were only secured in the slightest manner, did not move from their position, nor even when heavy charges or double shot were used, did sand and dust fall off their curved tops.

At a still earlier experiment made with a model of a 95-cwt. gun, the model was fired on the ice with excessive charges, and nevertheless remained stationary. This valuable concomitant of the system cannot be appreciated fully without referring to the difficulties that have been experienced, and are now felt, in getting pivots, platforms, etc., on the ordinary system, strong enough to mount the new artillery, where the recoil is stopped by friction applied directly by means of what are technically called *compressors* attached to the platform.

I shall not detain you by detailing these circumstances, but will only state that the first two 12-ton guns on ordinary carriages that were fired in casemates were both *hors de combat* the first shot. The accident referred to was serious, because it might occur in action, and in that event would disable the gun, *pro tempore*, as completely as if it had been dismounted by a shot. Some credit may be claimed for the new system, on the ground that it provided a carriage for a heavy piece of artillery on an entirely new principle, in which not a single part was copied from anything that had been formerly used, dealing with new conditions and performing the functions that no other carriage had done, and yet this new carriage (the first complete one of its kind) has now fired *two hundred rounds*. This practice has been carried on with only a few accidents which pointed to defects in the gearing, which were easily remedied. By treating this violent force in the manner above described, a good deal of the strength that is required in other systems becomes unnecessary. It will be observed that the interior slope of the parapet gives the most complete protection to the men, especially when the dome form is adopted.

Up to the present time the new system has only been considered as an improvement, and its value has only been estimated as an adaptation to existing forts, and there are no proposals for applying it *per se*. I am extremely anxious to impress on you and on my countrymen that its full value cannot be seen in this manner, and that it suffers injustice by being thus treated. I trust its proper use will be fully discovered before the inevitable lesson is dictated by war, and that it will be applied in works expressly designed for it, and not merely adapted to its use.

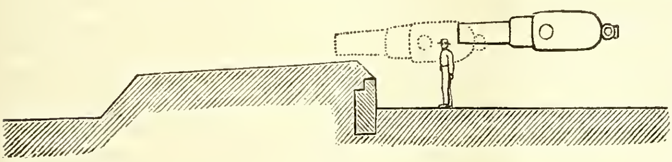
The third part of this system consists in its application to given positions and disposition of the batteries, and methods of working them in concert with and in support of each other. If I might be excused for using the paradox, this system of coast defense consists in the absence of any defined system; that is to say, instead of making large regular forts, and forcing surrounding circumstances into harmony with them, every accident of the ground in this case will be seized, where available, and small batteries, consisting of a few guns or of one powerful gun, laid down so as not to take away the natural aspect of the position. These batteries would be well retired from the channel, and placed so as to support each other in case of attack, and should, when circumstances permit, afford flank defense to each other, in conjunction with obstacles to the approach of the enemy. In connection with these gun carriages are some improvements of minor importance, such as trunnion pointers, reflecting sights, graduated races, and so on, which it would be out of place to discuss at present, but which contribute to the efficiency and completeness of the system, and are more or less required for carrying it out as a consisent whole for coast defense.

The second part of the system, viz: the profile of the batteries, is of the highest importance, because unless it is attended to great advantages are lost. This, unfortunately, makes the system extremly difficult of adaptation to existing works. In order to get the full advantage of it, no exterior slope of parapet should be exposed to the view of the enemy. This prevents him from being able to tell whether the fire be correct or wasted, and affords no means to him of correcting error. The battery, in fact, is masked; so that at some distance away, a moving ship would have considerable difficulty in laying her guns on one battery, and still more difficulty if there were several batteries judiciously placed for the purpose of deceiving the eye. It can easily be understood that the slighest error in elevation would either carry the shot harmlessly over the battery, or else cause it to ricochet off the glacis or superior slope. In fact, when the gun is down the enemy has nothing to aim at but an undefined horizontal line.

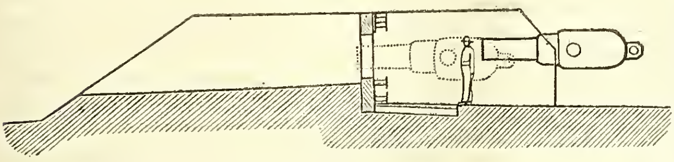
It is proposed to employ the Moncrieff batteries in connection with strongholds for infantry and light artillery, commanding, if possible, the sea batteries, so as to make them untenable by an enemy, and so placed as to be in the best position for a reserve, ready to support any point attacked; the whole connected with good and sheltered roads. In stopping the passage of a navigable river or channel, for instance, the guns, instead of being massed, would be scattered round the points where marine obstructions were placed. These guns would be disposed in such a manner as to retain as much as possible for the defense the advantages of a free lateral range, converging fire and different amounts of command. In other words, the method consists in placing in position the heaviest and most powerful artillery to the greatest advantage, making that the first consideration, and afterwards protecting the batteries, by separate and distinct arrangements easily devised by officers on the spot, against assault by any force that ships might land for that purpose When an object is to be obtained, I prefer to grapple with the most difficult and important part of it first, do that well, and meet the other requirements afterwards, with as little loss of efficiency as possible.

Sketch showing in section specimens of five methods of mounting heavy Coast Artillery.

BARBETTE.



SHIELD.



The first object of coast defense is to meet and defeat the attack of powerful ships; the next is to protect the shore batteries against landing parties. It must not, however, be forgotten that there are positions of such importance that they might be attacked by an army on land. Such positions must either be defended by another army placed in a favorable position by such arrangements as those above referred to, or else by regular and complete earthworks thrown up in time of danger, which would enable a still smaller garrison to resist anything but regular approaches. There are, however, few coast positions of such importance as to

draw the attack of a whole army; and such positions, as a rule, are now provided with regular works of a very high order; whereas there are many positions exposed to a naval attack, such as our large mercantile ports, etc.—They are almost invariably centers of population, which require only field-works and good small arms (which are now more powerful than ever) to repel the most determined attacks of any numbers that war ships could land. I believe many of the *present* coast works are defensible only against a *coup de main.* Wherever land attack is of more importance than naval, the character and efficiency of sea batteries must give precedence to those considerations which provide against assault. On the best provisions for meeting this I do not pretend to give an opinion. In such cases, the possibility of attack by both direct and vertical fire must be kept in view. Where my system is employed for arming such works, one or two precautions would increase the power of resistance. 1st. The large guns for operating against ships, with traverses and *parados* to each, should be kept as far apart as space will admit. 2d. Ample and thoroughly complete bomb-proof cover for the whole garrison should, if possible, be supplied in the middle of the work, with arrangement for interior defense (not barracks, but places for emergency) thoroughly secure from vertical fire—good and healthy barracks for the men being made independent of the works, and by preference kept out of the way. 3d. Howitzers and light artillery ought to be kept in reserve, in bomb-proofs constructed for the purpose, and (with the new system this can easily be done) also with the means of changing these to any required face.

The dispositions of defensive batteries, such as those I have very imperfectly attempted to describe, would not be complete without good arrangements for internal communications, not only by roads, but by telegraph, with a clearly laid down and simple method of working them; that is, not liable easily to go wrong nor to lead to mistakes, and which would not require very high skill. Such arrangements would increase the power of the defense, and indeed would be necessary with the detached system. I have accordingly given them some attention, and designed a general plan of laying off the ranges and working the telegraphs, which will make it possible to supply simultaneous information. The system I refer to (which has been submitted to the Director-General of Ordnance) would apply to any position, but its particular application would vary in each case. It is extremely simple. One part of it depends on electrical instruments which I have invented for the purpose, and which, without either calculations or experience, give the range and positions of an indicated ship at every gun in the position.

Another part of it enables the officer directing the defense to deliver in one instant, by the touch of his finger, a converging volley from one or both sides of a channel on a vessel sailing past. The possibility of delivering correct fire in this manner on a moving object, without aiming, and by an officer not even in the battery, was illustrated in one of my experiments with the 7-ton gun carriage at Shoeburyness; and I trust I may be given some day a chance of showing to what perfection this system can be carried. Methods of determining the distance of vessels from batteries are practiced here and in some continental countries. My method is designed to be quicker, simpler, and therefore more effective. It is adapted to work in conjunction with the arrangements for sub-marine mines. That part of it which gives the required information for sighting the guns is of so simple a character that the most uneducated gunner cannot make a mistake in its application. There are many other features of the system besides those I have particularly referred to which I shall not now discuss; each requires different treatment. Among these there are methods of mounting guns in ships, floating batteries, Moncrieff carriages for heavy guns of position, adapted for locomotion, for coast defense and for siege carriages.

AMERICAN LOCOMOTIVE BOILERS.—It is impossible for an English engineer to read the records of American boiler explosions without being struck by the very large number of failures of locomotive boilers which occur annually on the other side of the Atlantic. In this respect the American records form a strong contrast to those of explosions in this country. Here the number of locomotive boiler explosions seldom exceeds three or four per annum, and considering the large number of locomotives now at work in the United Kingdom, locomotive boilers may be said to possess a greater immunity from explosion than almost any other class. To a great extent this is, no doubt, due to the fact that locomotive boilers are, almost always, worked under skilled superintendence, and subject to frequent inspection; but it is also due to their being, with but few exceptions, well constructed in the first instance, and properly proportioned for the work they have to perform. In America, locomotive boilers, although under quite as skilled superintendence as our own, are yet more liable to explosion from the fact of their having generally less superfluous strength when new than would be considered necessary by our railway engineers. American locomotive superintendents use $\frac{5}{16}$ in. and $\frac{3}{8}$ in. plates, where we should use $\frac{7}{16}$ in. or $\frac{1}{2}$ in.; and notwithstanding the high pressures used, double riveting is still the exception rather than the rule. The consequence of all this is that in a list, now before us, of 94 boiler explosions which occurred in the United States during 1868, no less than 23 explosions of locomotive boilers are recorded, these explosions thus amounting to over 25 per cent of the whole; while from another record of the explosions which took place in the month of May last, we find that during that month four locomotives exploded on different American lines. These are facts which demand the serious consideration of American locomotive engineers, and we trust that in the records of future years we may find evidence that the lessons which they teach have not been disregarded.—*Engineering*.

STATION ROOFS.—The large number of the members of the Institution of Civil Engineers will recollect the interest with which Mr. J. W. Barry's paper on "The City Terminus Extension of the Charing-cross Railway" was received at one of the meetings in the spring of last year. The paper and the discussion upon it has lately been issued to the members, and its re-appearance, in printed form, will revive, to some extent, the arguments advanced at the time referred to. A certain number of the speakers made common cause against roofs of large span, upon the sole ground of their cost, an objection equally applicable to the dome of St. Paul's, or the grand façade of the *Παρθενος*—the vestal temple of the goddess of Engineering, engineering being understood in its true Minervian sense of wisdom, war, and the liberal arts. Considered as a roof merely, a roof of great span costs more than a series of roofs of smaller span covering the same area. But, taking the roof as a part of a costly building, the difference of cost between a roof 200 or 300 ft. span, and two or three roofs of, respectively, one-half or one-third the span, is relatively small. The weight and cost of the principals alone rise in proportion of the square of the span, being, say, twice as much for a single span of 250 ft. as for two of 125 ft. The roofing or covering is of the same weight and cost, no matter what the span. In station roofs of from 212 ft. to 240 ft. span, the weight of the principals varies from one ton to one and a half tons only per running foot of the length of the building, so that in a roof even 800 ft. long, the saving by making two spans of 120 ft. instead of one of 240 ft. would not amount to more than the saving of from 400 to 600 tons in the principals, with the expense, on the other hand, of say, 150 tons of cast iron in forty intermediate supporting columns. The narrower spans are in any case the cheaper, but the utmost cheapness is not a *sine qua non* in buildings of a monumental character. Few genuine engineers, loving their profession for its own sake, would argue the contrary. Indeed, in the very discussion to which we refer, the arguments to the contrary came from a somewhat unfortunate contractor, and from the engineer of a non-dividend paying railway; an engineer who, having by his writings set up some pretensions to authority upon station construction and station architecture, has nevertheless given to the metropolis one of the ugliest works of its kind of which London has to be ashamed. Although, at present, works of associated private enterprise, railways are really as much public works as are the Government offices themselves, and, as public works, something beyond bare convenience is to be considered in railway-station architecture. The pretense that railway stations are unworthy of architectural treatment—a pretense often advanced—is in itself unworthy of our profession, unworthy of railway enterprise, and unworthy of public taste. And it is out of the question that a series of low, narrow-span sheds, such as might be run up for a manufactory or a warehouse, can be considered as an architectural work. In stations of which the total cost, apart from land and compensation, is from £150,000 to £230,000, and where architectural effect is almost incumbent upon the engineer, the difference of from £3,000 to £4,000 in the cost of the roof, representing an interest charge of from £150 to £200 per annum, is not a subject for very grave discussion. Where from five to ten million passengers pass through such a station yearly, the cost to each passenger, at each journey, is but from, say, the $\frac{1}{150}$th to the $\frac{1}{200}$th part of a penny, or a penny for every 150 to 200 journeys, short or long, say a penny every three months for the season ticket holder entering and leaving the station daily six times a week. A daily traffic of from 20,000 to 40,000 passengers, half in each direction, is nothing very remarkable "in and out" of a great Metropolitan station. The cheese-paring engineers, of whom there are a good number, may, possibly, in view of such easily established facts, condescend to admit that considerations of grandeur and general effect, attended also with greater convenience, comfort and safety, should be allowed to have some weight in station design.—*Engineering.*

TURBINE TESTS.—Frequent inquiries are made for full and trustworthy data regarding the economy of turbine wheels, especially the new wheels so vigorously advocated of late. Some of these have merit we believe, but the public require better proof than interested statements. A commission of engineers, whose ability and character are above suspicion, should be asked to undertake tests at the joint expense of the wheel makers. Such a trial would be exhaustive and convincing, and moreover it would greatly stimulate the turbine wheel trade.

SEWAGE CARRIED BY WATER.

From "The Artizan."

The transporting power of water, when conveying sewage, is becoming a subject of very great importance, as both the fertility of the soil and the sanitary state of our large cities are affected by it. It is now pretty generally admitted, that plants can best absorb nourishment from the soil when the soil receives the manure in a liquid form; but it also would appear that vegetables do not thrive so well when the water is very highly loaded with sewage.

There would, therefore, seem to be some certain proportion of water and sewage best adapted for the soil to absorb and again to give it off to the plants; and possibly this very proportion is also the best when water is the medium by which the sewage is transported, while at the same time it may be found that a city requires just this quantity of water to insure proper sanitary measures being carried out.

It is self-evident that the refuse of our cities could not be made to flow without water—be the slope or head of pressure ever so great; and also that pure water will flow with almost an imperceptible slope, but under such circumstances this pure water could not hold in suspension any foreign matter. Again, as it is necessary that sewage should be conveyed under ground for sanitary reasons, and that to utilize this sewage for irrigation it will require, under most circumstances, to be again pumped up, the question is, what is the velocity, in other words, the slope or head of pressure that should be given, which will require the least power to be expended in pumping?

If too little water be used, we must increase the fall, while too much of it involves needless pumping. It is, therefore, quite possible that it may be discovered that the proper liquification of sewage, so as to have the least expenditure in pumping, may be also the very same proportion per head required by our cities for sanitary purposes, as well as the very best proportion for agriculture.

The question, though very complicated, is one of great interest; and its importance is becoming more and more evident. That the soil can, when irrigated by sewage water, absorb the foreign matter, and give it out again in the best possible state for the growth of plants, is admitted, while the water being relieved of this matter, sinks into the ground below in almost a pure state; so this very water, which has been taken from a river high up in its course, can be made to supply our cities; then convey away the refuse, distribute it over the fields, adding to their fertility, and again return to the parent stream through the underground springs in a state to aid rather than injure navigation, for it brings no foreign matter along with it.

According to Beardmore, a bottom velocity of 40 ft. a minute will sweep along coarse sand, and 60 ft. fine gravel, but this is with pure water not already loaded with solid matter. What may be the necessary velocities with various loads of solid matter held in suspension, are questions yet to be determined by experiment. So as water holding sewage matter in suspension must be affected by the load it has to carry, the velocity requisite for sweeping along coarse sand under such circumstances, must be much greater than if only pure water was the disturbing medium.

For the sake of argument, suppose that a mean velocity of 1 ft. per second is the necessary velocity in a closed pipe, the question is, what is the size of pipe required to convey away the sewage of a given number of inhabitants?

Let this number be 100, and that two cubic feet of water (rather over 12 gallons) is the water supply for each man, woman, and child, during the 24 hours.

Now, as eight out of the 24 hours is required for sleep, there remains only 16 hours of the day that the greater portion of the sewage is supplied, and during certain hours of the day there must be a greater discharge than at others; allow one-fourth more to be deducted to admit of the maximum discharge, or in all only 12 hours.

The rate of discharge per second would therefore be

$$\frac{100 \times 2}{12 \times 60 \times 60} = .048 \text{ cubic feet,}$$

or 82.944 cubic inches, which it is supposed requires a mean velocity of a foot a second, that is 12 inches; so $\frac{82.944}{12} = 6.912$ sqr. inches is the sectional area required for a pipe to discharge the sewage for 100 inhabitants; or a three-inch pipe is sufficient to pass off this maximum discharge of sewage of 100 men, women, and children.

Again, suppose that the ground is such that there is *no available fall* along the line this sewage has to be discharged, and the length of pipe is 500 yards, the question is how to obtain the velocity of one foot a second?

Adhering to Beardmore's tables, the discharge being .048 feet a second, or 2.880 ft. a minute, distance 1,500 ft., and diameter of pipe 3 in., there is

$$\frac{1,500}{\left(\frac{73.6}{3}\right)^2} = 2\tfrac{1}{2}$$

That is, with $2\frac{1}{2}$ ft. head of water and a three-inch pipe (which is 500 yards long), in 12 hours this pipe could discharge the sewage of 100 inhabitants, but if the head of water was raised to 10 ft., this same pipe could discharge more than four times as much.

The question is, how is this fall to be obtained on perfectly level ground? and the answer is, by pumping; but it is obvious that *all* the water does not require to be pumped, but only a small portion of it, by simply having all the water-closets in a house above the level of 10 ft.; and whatever water may be used in the kitchen or ground floor only, can be pumped up to the required level, a work that would hardly occupy the kitchen servants above a quarter of an hour daily. There will also be this advantage, that, having to pump up all the dirty water in the sink or cesspool, no bulky matter could find its way *up* the pump, but would have to be removed by hand to the ash-pit, to be carted away in a dry state; thus there could be no danger of the sewage pipes ever being blocked up by solid matter.

Mr. Chadwick, in his report on the Paris Exhibition on dwellings for the working classes, has drawn attention to a number of most important sanitary questions, of which the above is one of them, and at page 76 of this able report points out, that fresh sewage that has not undergone the process of decomposition is not only more valuable in its fructifying power in the proportion of one to three; but, instead of killing fish when it escapes fresh into a river, the fish come and feed on it. So the question is, why is it that there has been so great an outcry about the evil effects of the sewage of our cities?

The reply is, that it is from a want of a proper knowledge of the abrading and transporting power of water, and to prove this, one example will be sufficient. At a well-known watering-place on the west coast of England, the local board of health are at present constructing a culvert to convey away the drainage and sewage of a portion of the town. The land is nearly level, so there is no great outfall that the sewage and drainage can flow off quickly by its own gravity. To provide, therefore, for this want of natural fall, the channel along which the sewage and drainage is to escape is made large, the culverts being 2 ft. by $1\frac{1}{2}$ ft., of egg-shaped section. The houses for which this sewer is being built are twelve in number, containing something rather under 100 inhabitants, and this drain is 500 yards in length, which will cost somewhere about one pound sterling per running yard, which, at five per cent, is an annual tax of rather over £2 a house.

Now the first mistake made in this town, we are of opinion, is combining the storm with the sewage drainage; for the former could, with impunity, be permitted to drain into the sea; but this mistake probably arises from a want of a proper knowledge of the abrading and transporting power of water, for if the storm drainage has already got its proper load of solid matter, where probably the slopes over the surface are much greater than within the culverts, it is evident that the highly charged storm water cannot aid in scouring out any prior deposit, but will rather add to it. Consequently, the admission of this storm drainage rather tends to block up the culvert sewers instead of keeping them clear, so there can be nothing gained by having large sewers to convey away the storm drainage also.

It has been said that the sewer now being built has a section of 2 ft. by $1\frac{1}{2}$ ft., but taking the nearest size to this, 2 ft. by $1\frac{1}{4}$ ft., given in Beardmore's tables, where there is a fall of 2 ft. in the mile, with a depth of 12 in. of water in the culvert, we only get a velocity of 59.9 ft. a minute, or what we started with, as required to move along sand by sewage water; but we also find that to give this depth of water, the discharge requires to be no less than 52 ft. a minute, or eighteen times more than the sewage of one hundred inhabitants, while with any decreased velocity it is supposed sand cannot be transported. The natural consequence is, therefore, that the sewer must get filled up, till it has reduced the opening to such an area that the velocity acquired by having to pass through such a small opening, can enable the water to sweep along sand, or, in other words, the culvert sewer gets filled up with decomposed putrid sewage, that poisons the air, earth, and water, while for some one-tenth of the cost probably, a proper system of sewage pipes could be laid down, so that even a new set of pipes could be laid down every other year at no greater cost than the interest on capital laid out on the culvert sewer.

By this head of pressure system also, it is evident that for irrigation purposes there would be little trouble in spreading the sewage over the lands, while by the increased velocity the land would receive it in a fresh state, and thus the greatest benefits to the soil would be secured without any deteriorating effect on the health of the inhabitants, and all at what cost? Merely that the kitchen servants, for a quarter of an hour or so daily, would have to pump up the water in the cesspool to a higher level of some ten feet or so above the sewage-pipe outfall, and thus all these ingenious methods of separating all sorts of rubbish would not be necessary, for they could not be pumped up from the sink, so that only paper in a state of pulp could pass down the pipes. The servants might at first object, but not where sewage arrangements are introduced for the first time, and once the advantage of this system were proved, all objections would soon disappear.

THE ALLOYS OF ALUMINUM WITH COPPER.

From the "American Horological Journal."

When Sir Humphrey Davy announced the fact that soda, lime, potash, magnesia, and the other alkalies were but oxides of a metallic base, it would have been deemed chimerical to have supposed that the discoveries he made by the expensive aid of the battery would at later date become of really commercial value. He did obtain both sodium and potassium in the metallic state. The substances in this form were new to the chemical world, still more strange to the popular. So new was it to the chemists that, on a globule of the reduced sodium being presented to a very distinguished chemist, he, with some enthusiasm, examined it; and, admitting the fact of its being a metal, exclaimed, "how heavy it is!"—when the real fact was that its specific gravity was less than water; the expression was the result of the general pre-conceived opinion that a high specific gravity was a test of a metallic body. It was reserved for a French chemist, Henry St. Claire Deville, to utilize the metal sodium, and that, too, in such a manner that the demand aroused attention to its production;—demand will inevitably bring a supply.

The original reduction was made by Davy by means of the voltaic battery. After it had been proved that these bases were really metals capable of reduction, chemistry brought all its resources to bear on the problem, and they were produced by other methods than the battery. All the processes adopted, however, were too expensive and laborious, involving an extraordinary amount of complicated manipulations with but inadequate results. The metal sodium, which is the immediate subject of our inquiry, long remained an object simply of curiosity or experiment in the laboratory.

The methods of reducing the metal have of late years been so simplified that, to quote Prof. Chas. A. Joy, in the "Journal of Applied Chemistry": "A few years ago a pound of this metal could not have been purchased for two hundred dollars, and even at that price there were few manufacturers hardy enough to take the order. At the present time it can be readily manufactured for seventy-five cents, if not for fifty cents a pound; and the probabilities are that we shall soon be able to obtain it for one-quarter of a dollar."

Deville found that by the reaction of the metallic sodium on common chloride of aluminum, a reduction was effected; the chlorine taking up the sodium, forming chloride of sodium (common salt), while the aluminum was left free in the metallic state. It is hardly necessary to go into the particulars of the process; but a metal well known to exist, had, for the first time, been brought to the world in such a condition of structure that its qualities could be tested, not only chemically, but mechanically. This was the direct result of Deville's metallurgic process of obtaining the reducing agent—sodium.

Aluminum in itself would be of but little use, so that a brief description will be all that is necessary. It is about the color of silver, but susceptible of a higher polish, especially on a fresh-cut surface; it is much less susceptible of oxidation than silver; its specific gravity is but little more than pine wood, and its tenacity, ductility, and laminating qualities are nearly equal to silver. Its use in the mechanical arts is limited, notwithstanding all these qualities, from the fact of its low point of fusibility, and at the heat of the fusible point being easily oxidized, so much so as to prevent soldering, except by an autogenous process. But aluminum does possess a property peculiar to itself—that of forming a purely and strictly *chemical alloy* with copper. It unites with it in any proportion; the compound formed by the addition of 10 per cent of aluminum to 90 per cent of copper has been found to possess all the properties of an entirely new metal, with qualities that render it a very valuable material in all fine work, such as astronomical instruments; and very fine machinery, such as watch-lathes, etc.

The French reports on the alloy are somewhat voluminous, but we give the following :

The color of this bronze so closely resembles that of 18 carat gold, such as is used for the best jewelry and watch-cases, that it is capable of receiving the highest polish, and is far superior in beauty to any gilding.

Samples taken from different parts of the largest castings, when analyzed, show the most complete uniformity of composition, provided only that the two metals have originally been properly mixed while in a state of fusion. These experiments have been made upon cylinders weighing many hundreds of pounds, and are entirely conclusive.

This valuable quality is not found in any of the more ordinary alloys of copper. The alloy of copper with tin, for example, known as *gun-metal*, is notoriously subject to a phenomenon known as *liquation;* in consequence of which a great difference is found in the composition of the same casting, both in the top as compared with the bottom, and in the center as compared with the circumference.

This phenomenon often causes great inconvenience, as the different parts of large objects will, in consequence, vary greatly in hardness as well as in strength. In casting artillery the difficulty becomes a serious one, and no means have yet been discovered by which it can be entirely removed.

This homogeneousness of aluminum bronze is a natural consequence of the great affinity existing between the two metals of which it is composed; and that there is such an affinity is clearly proved by the phenomenon attending the manufacture of the alloy. The copper is first melted in a crucible, and the aluminum is then added to it *in ingots*. At first there is, of course, a reduction of temperature, because the aluminum in melting absorbs the heat from the melted copper; and this absorption is so great, in consequence of the great capacity for heat of aluminum, that a part of the copper may even become solid. But let the mixture be stirred a moment with an iron bar, and the two metals immediately unite; and in an instant, although the crucible may have been removed from the furnace, the temperature of the metals rises to incandescence, while the mass becomes as fluid as water.

This enormous disengagement of heat, not seen in the preparation of any other ordinary alloy, indicates, not a simple mixture, but a real chemical combination of the two metals. The ten per cent bronze may therefore be properly compared to a salt, the more so as it is found by calculation to contain, within a very minute fraction, four equivalents of copper to one equivalent of aluminum.

The ten per cent bronze may be forged cold, and becomes extremely dense under the action of the hammer. The blades of dessert-knives are thus treated in order to give them the requisite hardness and elasticity. But it has another valuable quality which is found in no other kind of brass or bronze. It may be forged hot as well as, if not better than the very best iron. It thus becomes harder and more rigid, and its fracture shows a grain similar to that of cast steel. On account of the hardness of the aluminum bronze, rolling it into sheets would be a tedious and expensive process, were it not for this property of being malleable at a red heat. But it may in this manner be rolled into sheets of any thickness, or drawn into wire of any size. It may also be drawn into tubes of any dimension.

From several experiments, made at different times at Paris, it appears that the breaking weight of the cast bronze varies from 65 to 70 kilogrammes the square millimeter. The same bronze drawn into wire supported a weight of 90 kilogrammes the square millimeter. The iron used for suspension bridges, tested in the same manner, did not show an average of more than 30 kilogrammes. Some experiments were also made by Mr. Anderson, at the Royal Arsenal at Woolwich, in England, who tested at the same time the aluminum bronze, the brass used for artillery, and commonly called *gun-metal*, and the cast steel made by Krupp in Prussia. Taking for the maximum strength of the bronze the lowest of the numbers found, as above, we are thus enabled to form the following table of comparative tenacities :

Aluminum bronze, 10 per cent......	65
Krupp's cast steel................	53
Refined iron......................	30
Brass for cannon..................	28

The comparative toughness of these same four metals was also tested in the following manner: A bar of each was prepared of the same size, and each bar was then notched with a chisel to precisely the same depth. The bars were broken separately, upon an anvil, by blows from a hammer. The last three metals in the table broke each at the first blow, with a clean and square fracture. The aluminum bronze only began to crack at the eighth blow, and required a number of additional blows before the two pieces were entirely separated. And the irregular, torn surface of the fracture showed the peculiarly tough and fibrous nature of the metal.

The elasticity of the aluminum bronze was tested by M. Tresca, Professor at the *Conservatoire des Arts et Métiers*. The experiment was made upon a bar of simple cast metal, and the following is his report: "The co-efficient of elasticity of the aluminum bronze, the cast metal, is half that of the best wrought-iron. This co-efficient is double that of brass and four times that of gun-metal, under the same conditions."

The specific gravity is 7.7, about the same as iron. Another very valuable quality is presented in the fact that it is acted on by atmospheric influences less than are silver, brass or bronze. This places it in the same rank with gold, platinum and aluminum.

Very stiff and very elastic, tougher than iron, very little acted upon chemically, and in certain cases not at all, capable of being cast like ordinary bronze or brass, forged like iron and steel, of being worked in every way like the most malleable metals or alloys, having added to these properties a color analogous to that of the most precious metal, this bronze proves itself adapted to uses almost innumerable. At first sight, it seems difficult to admit that the relatively small proportions of aluminum which enters into the composition of this bronze can be sufficient to modify so extraordinarily the properties of the copper which constitutes so large a portion of its weight. But we must remember that the specific gravity of aluminum is very low, and that a given weight of this metal possesses a bulk four times as large as the same weight in silver. It follows from this that the ten per cent of aluminum contained in the bronze equals in bulk forty per cent in silver.

The specimens of the ware we have seen, such as spoons, forks, cups, watch-cases, etc., are certainly very beautiful, having the color and high polish of gold, while dilute acids do not affect the surface.

SUBMARINE RAILWAYS.

From "Engineering."

It is sixty years since Trevithick, undeterred by the unsuccessful attempt of Ralph Dodd, began a tunnel under the Thames, working from the Rotherhithe shore. He carried it upwards of 1,000 ft. under the river, and to within 100 ft. or so from the Middlesex bank, when the result of a rash experiment, undertaken by himself, was to flood the works with water. The history of the present Thames Tunnel, now about to become a railway tunnel, is sufficiently well known, and it is also well known that the Botallick mine, in Cornwall, extends for some distance beneath the Atlantic, and it is said that the miners can hear the roar of the waves, or, at least, the crashing roll of the shingle over their heads during storms. Our own columns have contained full accounts of the most important example of tunneling beneath water, viz: the Chicago Lake Tunnel, extending for two miles beneath Lake Michigan, and to a point over which the water is 40 ft. deep, the tunnel itself being 70 ft. beneath the surface of the lake. This work was carried through a bed of imperviable clay, previously bored at a number of points sufficient to establish its perfect continuity, and the tunnel was lined with brick work as fast as the headings themselves were advanced. Here the work was, from the first, as reasonably certain of success as its subsequent progress was easy and straight-forward.

The grandest example of subaqueous tunneling, should it ever be carried out, will be the submarine railway from the South Foreland to the French coast, near Calais. The under sea portion will be 22 miles in length (of course without shafts), under water of a maximum depth of nearly 200 ft. at high tides, and at a distance or depth of from 250 ft. to 320 ft. beneath the bottom of the Channel. A question of great present interest is, Can this tunnel be made? It is well nigh settled, beyond geological dispute, that there is no continuous bed of clay through which it can be carried, unless through a comparatively thin bed of gault of uncertain dip and direction—a bed which, from such examination as it has been possible to make, appears to crop out across the bottom of the Channel between Abbot's Cliff and Cape Blanc-nez. The designers of the Channel Tunnel have preferred, therefore, the lower or gray chalk, and have proposed a line two or three miles only to the north-east of the out-crop just named, with its superior out-crop of green sand. The dip, to the north-eastward of all the strata, is quietly estimated at 100 ft. per mile, although there is not an authenticated axial (longitudinal) section of the Channel in existence, to show what is the real declension, to the north-eastward, of the strata of its bed. The proposed tunnel would pass under the deepest part of the Channel, between Dungeness and the North Foreland, while it would not permit of the shortest crossing, possibly and probably the shortest crossing is not practicable for a submarine tunnel. One enterprising projector would carry a tunnel through the green sand, but those who would carry it through the chalk would still be sailing very close to the wind, with the certainty that if a "fault" or fissure were met with, an irresistible stream of water, under from 200 lbs. to 225 lbs. pressure per square inch, would quickly dispose of all the work previously done. There are large, unmistakable and well recorded faults in the chalk beneath London, and, what with seismotive action—and we *do* hear of earthquakes even in England—there may be larger faults beneath the Channel. That men can be found, by hundreds, to work the headings of a Channel tunnel, need raise no doubt whatever. But that these men would ever come out of the headings, dead or alive, is another matter. If the headings once fail, all hope is well nigh lost. It is proposed, by the engineers to the International Commission, to make two headings from each coast, each 9 ft. square. Two headings are proposed, upon an assigned theory of ventilation, but it is clear that a single heading can be perfectly ventilated by compressed air, while it is certain that two parallel headings would but double the risk without economizing time. With a single heading, 9 ft. square, once safely carried through, there would be no great difficulty in enlarging it to a tunnel 28 ft. or 30 ft. wide. But the roof of this heading, occupying, perhaps, five years in making it, would present a surface for percolation of 24 or 25 acres, and it could not be bricked up as the work proceeded. One, two, or three years after a portion of the heading had been completed, a resistless torrent of water might suddenly come through, destroying not only the whole work, but all within it. To undertake such a work, even if it be not tempting Providence, is, at least, to incur tremendous uncertainties, considering that it would be through a comparatively unexamined bed of chalk, but two or three miles from the outcrop of half a dozen strata.

But supposing the heading, or a parallel pair of headings once made, and the tunnel afterwards made, as it could then easily be made, there would not only be nearly 30 miles of continuous tunnel for the passenger, but this would be upon a line involving a long and circuitous route to Paris. If Paris be the "objective point," it would at least be 25 miles further from London *via* Dover, by Mr. Hawkshaw's, than by Mr. Fowler's route, the latter a steamboat route. From London to Dover is 78 miles by the Chatham and Dover, and 76½ miles (*via* Sevenoaks) by the South-Eastern. To Folkestone the distance is 71 miles only. Yet the proposed tunnel is to be carried well to the east of Dover, say to the South Foreland, and instead of being directed well into the course of the Belgian and North German traffic, it draws short of Calais, and connects more directly with the line between Calais and Boulogne, making it well nigh the most roundabout route between London and Paris.

The Channel Tunnel, estimated at £10,000,000, involving an interest charge, at 4 per cent, of more than £1,275 per day, of 313 working days per year, would admit of any traffic, however extensive, would conduct it at the average working rate of 35 or 40 miles per hour, without detention by tides, fogs, storms or the chances of collisions. It is doubtful whether it can be made, equally doubtful whether it could ever "pay," except in the far distant future, with trains every quarter of an hour. That all trains would require to be lowered 500 ft. or 520 ft. at each end, and again pulled up through the same distance, is by no means an insuperable objection to the tunnel. Nor do we apprehend any insuperable difficulties in the way of draining or ventilating. Both, for anything we can see, may be easily, successfully and permanently managed.

On the other hand, an absolutely certain means of communication, for which nature has provided the "permanent way," if that term may be applied to a tidal sea, is already to be found between Folkestone and Cape Gris-nez, Audrecelles, Ambleteuse or Boulogne. The shorter the sea passage desired, the nearer must the route bear towards Cape Gris-nez. Indeed, Dover pier and Cape Gris-nez are separated by the least distance of any points between England and the Continent, say $17\frac{1}{3}$ knots. But Cape Gris-nez would not make a good landing place for steamers, and so for the Belgian and German traffic, the route would require to be drawn more towards Calais, and so for Paris, it would require to be drawn more towards Boulogne. Of all the existing routes, they are diagonal between two nearly parallel coasts ; in fact, there is no *direct* route across.

The railway ferry boats proposed by Messrs. Fowler and Wilson, would cross between Dover and Audrecelles, the latter about 7 miles north of Boulogne. By leaving Folkestone instead of Dover, they would save from $5\frac{1}{2}$ to 7 miles of land journeying on the English side, and by making the French port a short distance south of Cape Gris-nez, about two miles north of Audrecelles, they would reduce the sea journey to less than that now attending the Dover and Calais route. To the point named (or rather not named, as bearing no name) the steam service between England and France would be well nigh the shortest practicable. Four or five miles of railway on the French side would connect it with the existing Calais and Boulogne railway, one of the crookedest and worst in France, except between the proposed point of junction and Boulogne. It would be objected that this route would take vessels across the "Varne" and the "Ridge," or "Le Colbert," the most dreaded sand banks, next to the Goodwins, of all in the Channel. But by planting a sufficiently visible beacon on the head of the Varne, a course might be taken to the north-east of it, which would, at low water spring tides, carry over a vessel drawing 24 ft. with more than 40 ft. of water over the north-eastern end or head of the "Ridge."

The tunnel, estimated to cost £10,000,000, and attended with an interest burden of £1,275 per day, might, for twenty trains each way daily, be worked at a cost of less than £200 per day. To perform the same service, probably ten boats, costing each £100,000, would be required, and it is not perhaps far out of the way to allow £1,000,000 for the improvements of the ports of Folkestone and the inchoate port south of Cape Gris-nez, but a little north of Audrecelles. Upon these would rest the interest at 5 per cent, of £100,000 per annum, together with a further sum of £100,000 per annum for depreciation on boats. Beyond these sums would be the cost of repairs of boats, say £50,000, besides coal, wages, &c., bringing the whole, probably, up to nearly or quite £300,000. The boats would not prevent sea-sickness, and they would be more or less exposed to the risks of collision. They might run aground, especially in shallow harbors, and at low tide, and however fast they might be as boats, they would be slow as compared with railway trains, the more so as they would require a considerable interval of time in receiving and discharging their deck load of passenger and goods carriages. Still, this brief examination by no means exhausts the subject.

The Bessemer Manufacture in the United States.—The Pennsylvania Steel Works at Harrisburg are regularly making eight five-ton heats every day of twelve hours. This would be equivalent to sixteen heats, or 65 or 70 tons of ingots per twenty-four hours. Eight heats in twenty-four hours is considered fast work in England. It is now over eighteen months since a heat has been lost at these works through the failure of the machinery or refractory materials—a result more remarkable even than the large product. The new five-ton plant of Messrs. John A. Griswold & Co., at Troy, is nearly completed, and will have a greater capacity than any other in this country. The two-ton converter at these works is regularly making ten heats per 24 hours, which is good work for a single vessel. An 18-inch merchant mill, made very heavy and specially adapted to steel, has also been started by this company, and is now turning out bars up to four inches round or square.

Mr. John C. Thompson has resumed the superintendence of the Cleveland works. The Lewistown works are executing a large rail order for the Pennsylvania railroad. The Steel Works of the Cambria Iron Company, at Johnstown, are approaching completion, and will be, in many respects, the finest Bessemer works in this country.

INDICATOR CARDS.

FROM STANDARD AND EXPERIMENTAL ENGINES.

Compiled from the proceedings of the Association of Engineers and Architects.

A suitable description of the Indicator, by which the diagrams referred to in this paper were taken, may be found in C. T. Porter's "Richard's Indicator," published by D. Van Nostrand, of New York.

Diagram No. 1 is from an "Allen" Condensing Engine at the Paris Exposition of 1867. The waving of the expansion line is caused by the excessive momentum of the Indicator piston, due to the high speed of the engine, which cannot be taken up by the spring quickly enough to give the usual regular outline to the diagram. The irregular, nearly horizontal line at the top of the diagram was drawn when the indicator was attached to the steam chest, and shows the pressure of steam as slightly lessened when at the beginning of the stroke a large quantity passes into the cylinder. The atmospheric line is shown in each diagram extending beyond the ends of the rectangle. The spaces between the horizontal lines on No. 1 represent 4 lbs. pressure.

No. 2 is from a Reed and Cogswell oscillating engine. The slow and tardy opening of the steam and exhaust ports is clearly shown. In this 4 lbs. to each space.

No. 3 from a Lenoir Gas Engine. The gas and air pass into the cylinder through valves which close at about half stroke, and the mixture is then ignited by an electric spark, or by other suitable means. 8 lbs. to each space.

No. 4 from a non-condensing engine in a rolling mill at Trenton, and shows the result of an accidental displacement of the pin from which the paper received its motion. The engine has a heavy fly-wheel, and at the time when this diagram was taken, was running without load. The point of admission is at *s*; the opening of the exhaust is at *e*; the back pressure against which the return stroke is performed is shown by the line at *a*; and the rise of the line from *a*, toward *s*, is due to the compression occurring in the cylinder before the beginning of the next stroke.

No. 5 from the U. S. gun-boat "Algonquin," with a Sickles cut-off. 4 lbs. to each space.

No. 6 from an engine having a poppet-valve cut-off, tripped by the action of the governor. 4 lbs. to each space.

No. 7 from the steam cylinder of a condensing blowing engine at Harrisburg, Penn. 6 lbs. to each space.

No. 8 from the air cylinder of the same engine, having valves made of a rubber band, opened and closed by the pressure of the air. 6 lbs. to each space.

Nos. 9, 10, 11, and 12, are all from a non-condensing Corliss engine, at Trenton, New Jersey. No. 9 shows the distribution of the steam by the valves as they had been set for many months previous to the application of the Indicator; and Nos. 10, 11, and 12 give the improvement shown by its use to be needed and entirely practicable. It was effected by merely moving the eccentric ahead upon the shaft so that the valves were all opened earlier. In all these, 6 lbs. to each space.

No. 12 shows a high back pressure with the engine following full stroke. No. 11, the distribution of steam when cut of at $\frac{1}{4}$ stroke, and No. 10, when no work was done except driving a fly-wheel and gearing, by which the power was transmitted to the train of rolls.

LEAD AS A COVERING FOR ROOFS.

By Mons. C. Détain, C.E., in "Revue Générale de l'Architecture."

Properties of Lead.—Lead is of a bluish-gray color, usually dimmed after being submitted to the action of the air, but lustrous when recently cut or scraped. It remains unchanged for some time in a dry atmosphere, but if subjected to the action of humid air it soon becomes covered with a blackish pellicle. This coating preserves the rest of the metal from oxidation, in the same way that a covering of the same nature preserves, with even greater efficacy, zinc surfaces. "Pure lead is not affected by perfectly pure water free from air, but if air be present the metal is oxidized at its expense, and the oxide thus formed, combining with carbonic acid, is deposited on the lead in minute crystals as a basic carbonate of lead. The water will then be found to contain lead in solution, and such waters drawn from impure cisterns, often produce very distressing consequences. If the water contains any sulphates, the lead is thrown down as a sulphate of lead, which is insoluble." ("Ure's Dictionary," 6th edition.)

In a state of purity lead is very soft—it may be scratched with a finger nail, and readily cut with a knife; rubbed upon paper it makes a metallic gray stain. Its malleability is very great, so great that it may be beaten into thin leaves and drawn into very fine wire, but it has but little tenacity—only about one-fourth that of zinc. A wire of one-twelfth of an inch diameter will not support 20 lbs. Lead which has been prepared by the old method, that is to say, by casting, much in the same way that plate glass is manufactured, has about the same tension as rolled or milled lead, but the cast lead breaks abruptly, presenting a clean, granulous fracture, whilst rolled lead, before giving way, is drawn into threads, so to speak. The rolling process has a great influence upon the ductility of this metal. The result of numerous experiments is that relatively laminated lead is to cast lead as 7 is to 5. The ductility of the latter kind appears to be the same for all thicknesses, whilst that of laminated lead appears to increase with the hammering to which it is subjected. Cast lead is firmer and drier, as the workmen say, than rolled lead. Its surface is marked by an infinite number of minute pores, which give it a rugose appearance. Rolled lead, on the other hand, has a very smooth surface.

The density of lead when pure is 11.445. The lead of commerce, however, is very rarely pure; it very often contains copper, iron, and even traces of silver, antimony, arsenic, sulphur, &c. Thus its density rarely rises above 11.352—one and a half that of zinc. Hammering does not appear to increase the density of lead, it diminishes it rather. It commences to fuse at 325° C.; before fusing it is covered with an iridescent pellicle of great beauty. As the temperature rises the colors disappear—at 335° C. it is in a complete state of fusion.

The prolonged contact of lead with another metal, will lead to its being destroyed by the electrical action which is set up. M. Détain quotes a case which came within his experience. The roof of a bathing establishment was covered with copper, but at one point lead was used in contact with the former metal. After a time the roof began to leak. A workman was called in. The lead was found completely oxidized; it had kept its form, but on being touched it crumbled into powder. The lead was likewise in contact with an oak plank, and its destruction was due to three causes: contact with the damp wood, the action of the vapor of water, and electrical action.

Lead is very rapidly altered by contact with damp plaster; sulphate of lead is then formed, which is a most energetic oxidizing agent. Saltpeter or niter also attacks lead very powerfully. Saltpeter is very often to be found in damp cellars, and upon the walls of wells; thus it is very commonly the destruction of the lead pipes in pumps, which under these attacks become perforated in many places. Again, lead is subject to the attack of certain insects which gnaw very minute orifices in it. It appears that old lead is not so liable to these attacks, and the inferiority in this respect of modern lead, is attributable to its being now-a-days too much refined, which, together with the rolling process, tends to weaken its structure. The texture of rolled lead is, so to speak, formed of a number of leaves, which are capable of being separated without much difficulty. Nevertheless, laminated lead is not the sole kind liable to these insect attacks. Marshal Vaillant not long since presented to the French Academy of Sciences some bullets which had been deeply eaten into in this way. Lead has about half the heat-conducting power of zinc. The power of lead, in this respect, is represented by 180, that of zinc by 363.

Nearly all the lead which is employed in the arts is extracted from the ore called galena or sulphide of lead. "This is the most abundant ore of lead; it may be, indeed, regarded as the only commercial ore of any value, if we except the carbonates, which are probably formed by the decomposition of galena."—("Ure's Dict.") This ore is found in all the lead producing districts. Thomson's analysis of galena gives:

Lead	85.13
Iron	0.50
Sulphur	13.02

Lead is found in almost every country. The beds are numerous, and next to iron the most widely spread; but the richness of these beds is very unequal. It is found almost in every kind of stratum, sometimes in thick and productive seams, sometimes only in "pipe veins," sometimes disseminated in grains.

England and Spain are at the head of lead-producing countries. England produces 70,000 tons; Spain 60,000 tons; Germany produces only about 10,000 tons; France produces but the insignificant amount of 200 tons annually, whilst to supply her wants she has to import about 80 times as much more.

Lead in its employment for Roofs.—The layer of lead upon a roof must be sufficiently thick to resist the influence of the coating of oxidized matter which will overspread its surface under the action of the atmosphere, and also to resist being torn and cracked by the force of the contractions and dilations which variations of temperature may cause it. The tenacity of lead is four times less than that of zinc, and at the same time its linear dilation is the same. In order then that lead may present the same resistance as zinc, it must be four times as thick. It is true that lead resists the destructive action of winds more successfully than zinc, on account of its greater weight and its better adherence to its supporting timber; but this very weight may prove an element of its early decay in the case of roofs which are of a very steep incline. We must also take into account that a roof covered with lead will cost six times as much as one in which zinc is used. Nevertheless, in making a comparison between the monetary value of lead and zinc, we must always remember that there is a vast difference in the ultimate intrinsic value of the two metals; lead after being used loses but little of its first value; whilst zinc loses considerably more than one-half.

If a lead roof is heavier and dearer than one of zinc, it is superior to it in appearance. It very quickly assumes a uniform dark aspect with grayish reflections; whilst zinc very slowly puts on a dirty black color, without any reflections. No experienced eye could be deceived as to the two metals, even at some distance. Lead has a rich, substantial look, whilst zinc is characterized by a mean, flimsy and cheap appearance, which must greatly detract from the beauty of any building of importance. The roof of Notre Dame, which is formed of lead, has a beautiful appearance, to speak of its color alone; the roof of St. Clotilde, on the contrary, formed as it is of zinc. has a poor and commonplace look. This fact is so fully admitted by the French builders, that in Paris, where, in house building, zinc is largely employed, those parts which are very prominent are colored black to resemble lead. This coat of oil paint, however carefully it may be prepared, adheres only badly to the metal, for in a short time it scales off and falls away in pieces. Another process has been tried with much effect, as it has been alleged. This is to paint the zinc with a hot solution of graphite, in water strongly charged with caustic and fixing substances, as for example, chlorate of potash and sulphuric acid; 14 parts of graphite, 1 of chlorate of potash diluted in 28 parts of sulphuric acid, commonly called vitriol. The whole of this compound must be gently heated, and watered to a consistency such as may be easily laid on with a brush. It is a good method, first of all, to wash over the surface of the zinc with a weak solution of sulphuric acid, which will cause it to take the paint more perfectly. The paint must be laid on hot.

Formerly, the lead was of a thicker kind than that now in use. This is one of the reasons why modern leaden structures are less durable than the old. Besides having regard for the proper thickness of the sheet of lead, we must always take into account the special qualities of the metal. Thus, when it is placed in position where it may expand with facility, we must, if possible, only nail it upon one end. The nails should be of a large head, and placed closely together. Lead should never be placed in contact with wet wood or damp plaster; and the proximity of another metal less oxidizable, should always be avoided. Finally, lead should never be subjected to the action of the vapor of water, because the water upon being condensed upon the surface of the metal is very much aërated, and in this condition acts very energetically upon lead, as we have already seen.

Soldering.—Lead is soldered by means of an alloy of that metal with tin, or simply by itself without the employment of any intermediary alloy, by the method known as "autogenous soldering." For the soldering of large and heavy work, the proportions of the alloy should be 30 tin and 70 lead; for lighter varieties of workmanship, 70 tin and 30 lead.

With respect to autogenous soldering (lead with lead, without using any intermediary alloy), it is only made use of in very great works, and in producing leaden vessels for the manufacture of chemical products, where the acids which act upon tin would very quickly destroy the ordinary solder.

This new method of soldering was invented by Count Desbassayns de Richemont. "Hydrogen gas is contained in a gasometer to which a flexible tube is connected, and air is urged from a bellows worked by the foot through another tube and on to the blowpipe where the hydrogen is ignited. By means of the flexible tubes, the flame may be moved up and down the line of any joint, and the connecting medium melted."—(Ure's Dictionary.) In our naval arsenals this process has been largely employed. This kind of soldering renders the joint very strong, the junction being as firm as any other part of the surface of the metal. The process is capable of being used in all kinds of plumber's work.

In France, especially, lead roofs are formed in two ways: In the shape of slates and used in the same way, and in sheets. Leaden tiles are used only in the case of very pointed steeples, or domes of small dimensions, and in analogous circumstances. When sheet lead is used on steep roofs, it must be firmly secured, and at the same time it must be allowed the means of dilations. The new roof of the Cathedral of Notre Dame, at Paris, is made of cast lead. The celebrated Dome of the Invalides, in the same city, recently repaired, is likewise of cast lead. Both these roofs have a deservedly high reputation for beauty of appearance and excellence of workmanship.

THE IRON AGE OF SHIP-BUILDING.—The first large, square-rigged iron sailing-vessel ever built in this country was successfully launched August 5th, from the yard of Messrs. Harlan & Hollingsworth, at Wilmington, Del. This vessel, a bark, was built for Messrs. Tupper & Beattie, of this city, and is said by competent judges, who have examined her, to be in every respect equal to the best Clyde-built ships. She registers 700 tons, new measurement, is 155 ft. over all, 140 ft. keel, 31 ft. 9 in. beam, $11\frac{1}{2}$ ft. depth of hold, is 7 ft. between decks, has all the modern improvements, and is very appropriately named the Iron Age. She has a yacht stern, upon which is placed the attractive and appropriate coat-of-arms of the State of New York. Her prow is sharp, and has for a figure-head the bust of an artisan, with a cold-chisel in one hand, and a hammer in the other, emblematic of his craft.

This vessel was built upon British specifications, and at a cost, we are assured, not exceeding the best Clyde-built ships, or, indeed, the cost of constructing a first-class wooden ship at this port at the present time, a special contract rate having been secured. In several essential particulars the Iron Age is an improvement upon any British iron ship which has visited our ports. The angle iron used in her construction is considerably heavier than that employed by the Clyde and Mersey builders; her ribs are from two to four inches closer together than British ships, while in her framing there has been no piercing or bursting of rivet-holes, which is something unusual in this class of vessels. In point of model, sailing qualities and carrying capacity have been judiciously blended. All the British iron ships that we have seen, are long and narrow, thus rendering it necessary to ballast them before receiving, and after discharging cargo. The Iron Age has sufficient breadth and curvature to obviate such a necessity. She has already been surveyed by the agents of the American and French Lloyds, and pronounced by them one of the best specimens of iron ships. When launched and ready for rigging her draught of water was only 4 ft. 11 in. forward, and 6 ft. aft, which is a foot lighter than a wooden ship of the same dimensions.

While the first cost of an iron ship is greater than that of a wooden vessel of the same size, the former, in the end, is much the more economical. It has been abundantly demonstrated that the use of iron instead of wood gives to the vessel greater strength, combined with lightness—two important considerations in ships. An iron ship, moreover, is not subject to the intense straining which is so severe upon the joints of the wooden vessel. The facility which iron gives in the construction of a vessel is much superior to that of wood, because there is no useless metal employed, and no filling is required. The power of iron to resist tension and compression is also much superior to that of wood. In the preparation of the material for the construction of a vessel, there is great economy of time and labor in the use of iron. The superior strength of iron vessels, and the tenacity of their frames in contingencies fatal to wooden vessels, are illustrated by a long practical experience. The use of iron increases the capacity of the vessel for stowage, thus rendering this kind of tonnage far more profitable, to say nothing of durability. A first-class wooden ship will rate A 1 for but nine years, while a first-class iron ship will stand the same rate for twenty-one years. And the iron ship, with no unforeseen casualty, will be good property long after a modern wooden ship has gone out of existence.

The days of wooden ships, it is safe to conclude, are about numbered. In Great Britain, iron has become the standard material for ship-building, and in other maritime countries a similar change is beginning to take place, so that in another decade, probably, wooden ship-building will be out of date. Although the United States, for obvious reasons, is behind the leading nations of Europe in this branch of industry, it may safely be taken for granted that we are not likely to remain long in the background. We want cheaper materials to begin with, and if Congress cannot frame a law for the benefit of ship-builders without exciting a conflict of interest among other classes of home producers, it must inaugurate prompt reform in national finances, such as shall bring down the cost of production to its natural level. Something must be done, without longer delay, to resuscitate an interest that has been, in years gone by, the bulwark of our commerce, and to rescue our valuable carrying trade from the flags of other nations.

The Iron Age is the third iron sailing-vessel ever built in the United States, the other two being the schooner Mahlon Betts, built at Wilmington, Del., and the iron brig Novelty, recently built by the Atlantic Iron Works, Boston, for carrying molasses in bulk. Both are much smaller than the vessel launched at Wilmington last week.

Wilmington has important advantages over any other American port in this branch of industry. She has iron and coal in abundance at her very door, together with long years of experience. The firm who built the Iron Age have built upwards of two hundred iron steamers, varying in size from 300 to 1,500 tons. They have built for one firm alone, twenty-one steamers for the Gulf trade, and they have been thirty-three years maturing their plans to carry on this important branch of industry. They employ at present 600 hands, but have facilities for employing more than twice that number, should their business warrant it.—*N. Y. Shipping List.*

RESISTANCE OF ROADS TO TRACTION.—The following results of the experiments of Sir John McNeill in regard to traction on roads of different kinds, are pretty generally accepted as accurate:

Resistance in pounds per ton on different roads.

Iron floor	8 lbs. per ton.
Stone tramway	20 lbs. per ton.
Paved road	33 lbs. per ton.
Macadamized road	44 to 67 lbs. per ton.
Gravel	150 lbs. per ton.
Soft, sandy and gravelly soil	210 lbs. per ton.

STEAM-ENGINE PERFORMANCE.

From "Engineering."

Since the publication in a recent number* of the particulars of the experiments made by Messrs. Farey and B. Donkin, jr., on an engine at Messrs. B. Donkin & Co.'s works at Bermondsey, we have received from Mr. John Pinchbeck the details of a trial conducted by him some years ago of a single-cylinder engine constructed by the Reading Ironworks Company, then Messrs. Barrett, Exall & Co. In this trial the temperatures of the water supplied to, and thrown off from the condenser were accurately noted, and the quantities both of the condensing water and of the water evaporated were carefully weighed, as was also the fuel used. In order that the quantity of water evaporated might be ascertained with accuracy, the water was weighed before filling the boiler, and on the experiment being completed the boiler was blown off, and the water thus blown off also weighed. The difference between these first and final weighings had, of course, to be added to, or subtracted from the weight of the water supplied to the boiler during the trial, in order to get the true evaporation. The weighing of the water discharged from the condenser was managed as follows: A wooden tank, measuring about 4 ft. × 4 ft. × 4 ft., was placed on the table of a weighing machine and accurately balanced, and weights amounting to one and a-half tons were then placed on the scale beam. The water in the condenser was then run into this tank until the weights we have mentioned were lifted, when the communication with the hot well was shut off by a sluice, and another sluice opened which allowed the water to run out of the tank. While the main tank was being emptied, the water discharged from the hot well was received in a small auxiliary tank, which was, of course, emptied into the main tank as soon as the latter was ready to be refilled. The number of times that the main tank was filled and emptied was, of course, registered, and the weight of water discharged from the condenser was thus obtained very accurately. Altogether this trial of a single-cylinder engine is one which forms an interesting comparison with that of the engine of the double-cylinder class, of which we gave the details last week. The particulars of Mr. Pinchbeck's experiments are as follows:

* See V. N.'s Mag., Aug., p. 693, and Sept., p. 787.

Description of Engine.—Horizontal high-pressure condensing. Cylinder 21 in. in diameter, with 30 in. stroke. The cylinder and covers steam-jacketed, steam being supplied direct from the boilers, and means being provided for getting rid of the water resulting from the condensation of the steam. Distribution of the steam effected by slide-valve with adjustable expansion valves at the back, worked by separate eccentric. During the trial the cut-off took place at $3\frac{1}{8}$ in. of the stroke.

Boiler.—Cornish, 22 ft. long, 5 ft. in diameter, with single flue 32 in. in diameter. The boiler was fed from the hot well, the water being pumped through a heater fixed in the boiler flue.

Duration of experiment	10 hours.
Quality of coal used	Duffryn steam coal.
Quantity of coal used	11 cwt.
Quantity of water evaporated,	1,108 gallons.
Quantity of water evaporated per lb. of coal	9 lbs.
Pressure of steam	50.9 lbs. per sq. in.
Mean vacuum	27 in.
Quantity of water thrown off by condenser per minute	410 lbs.
Mean temperature of water used for condensing	38°
Mean temperature of water as discharged from condenser	82°
Revolutions of engine per min., by counter	60.03
Power developed (indicated)	47 H. P.
Power developed, as measured by brake	40 H. P.
Consumption of coal per hour per indicated horse-power	2.6 lbs.
Consumption of coal per hour per dynametrical horse-p'r,	3.06
Ratio of expansion, allowing for clearance, etc	1 : 8.6

It will be seen, from the above particulars, that the mean vacuum and the indicated power developed, are practically identical with those obtained during the trial of Messrs. B. Donkin's engine, and the consumption of coal per indicated horse-power per hour is also the same. It will be remarked, however, that the pressure of the steam is 10 lbs. higher than during Messrs. Farey and Donkin's trials, and that—owing probably to a better quality of coal being used—the evaporation of water per pound of fuel was higher than in the case of these last-mentioned experiments, being 9 lbs. against 8.72 lbs., and this circumstance should, as we pointed out in our previous article, be taken into consideration in comparing the performances of the two engines. Adopting the far better method of comparison proposed by Messrs. Farey and Donkin, and already fully described by us, we find that the quantity of heat discharged into the condenser, per indicated horse-power per minute, was more than 16 per cent less in the case of Messrs. B. Donkin and Co.'s engine, than in that of the engine tested by Mr. Pinchbeck. Thus, in the latter instance, the average quantity of water discharged from the condenser was 410 lbs. per minute. This quantity of water was heated from 38° to 82°, or 44°; and multiplying 410 by 44, we get 18,040 as the number which, divided by the indicated horse-power developed, gives Messrs. Farey and Donkin's "constant." In the case of the engine tried by Mr. Pinchbeck, this "constant" is $\frac{18,040}{47} = 383.8$, while the "constant" obtained during the trial of Messrs. B. Donkin & Co.'s engine was 322.87, or 16.2 per cent less. Considering that the quantity of fuel burnt, per indicated horse-power per hour, was the same in the two cases, and that the evaporative value of the fuel varied but about three per cent, the above difference of 16.2 per cent in the quantities of heat respectively received by the two condensers, appears, at first sight, somewhat difficult to account for, even if we suppose that in Mr. Pinchbeck's experiment the hot well received all the water discharged from the steam-jackets. If, however, we analyze Mr. Pinchbeck's experiment more minutely, we shall find that the various results agree very closely, and that any errors of observation which may have occurred, must have been very small. If this had not been the case, we might have supposed either that the quantity of water evaporated must have been somewhat greater, or the quantity of condensing water must have been less, or have been less highly heated during its passage through the condenser. Thus, 1,108 gals. of water were evaporated during the ten hours = 1,108 lbs. per hour = 18.46 lbs. per minute, and, of course, the same quantity of water returned to the boiler as feed at a temperature (the feed being taken from the hot well) of 82°. The total heat of steam, at a pressure of 52 lbs. above the atmosphere, is 1,205.4°, and the quantity of heat withdrawn from the boiler, per minute, was thus $(1,205.4—82) \times 18.46 = 20,737.96$, or, say, 20,738 thermal units. If now we suppose (as was probably the case) that the water discharged from the steam-jackets found its way into the hot well, the manner in which the above quantity of heat would be disposed of would be as follows: Subtracting from the 410 lbs. of water discharged from the condenser per minute, the 18.46 lbs. resulting from the condensation of the steam, we get 391.54 lbs. as the quantity actually raised in temperature 44°, and $391.54 \times 44 = 17,227.76$, or, say, 17,228 thermal units of heat are thus accounted for. Again, the quantity of heat actually converted into work would be $\frac{33,000 \times 47}{772} = 2,009$ units, and there would thus be but 1,501 units to be accounted for by losses by radiation, etc. The summary would be as follows:

	Thermal units per minute.
Converted into work	2,009
Imparted to condensing water	17,228
Lost by radiation, etc	1,501
	20,738

We have said that the difference of 16.2 per cent in the "constants" obtained in the two cases we have considered is, under the circumstances, somewhat difficult to account for; but it is no doubt due to the fact that, not only was the expansion carried to a less extent, but both the initial and final temperatures of the condensing water were, in the case of the engine tested by Mr. Pinchbeck, lower than in the case of the engine at Messrs. B. Donkin & Co., although the vacuum was the same in both cases. Of the effect of such differences of temperature and of the degree of expansion on the "constants" proposed by Messrs. Farey and B. Donkin, jr., we intend to speak fully on an early occasion; and we shall then show that the fact of such differences having the effect we have stated, in no way diminishes the value of the "constants" as standards of comparison, but, on the other hand, rather increases it.

FRENCH MILITARY TELEGRAPHS.

Translated for "Engineering" from "La Télégraphie Militaire," Paris, 1869.

The following are details of the military electric-telegraphic apparatus used in the experiments in the camp at Chalons, last summer:

Electric Telegraph.—For military purposes it is desirable that the apparatus should not only be simple in itself, but should be capable of being used in connexion with the permanent lines of telegraph already established. Keeping these ends in view, a modification of Morse's recorder, constructed by M. Duguy, from designs furnished by the Bureau des Télégraphies, and known as Le Poste Militaire, was adopted and found to answer well. This apparatus is contained in a box, to the bottom of which it is secured by slides. The manipulator is placed on the right of the small shelf supporting the recorder; on the left are the galvanometer to show the strength of the current, and a paratonnère to protect the operator from the shock of unforseen accumulations of electricity in the wires in stormy weather. The sides and front of the box fold down, so as to permit of the instrument being used without necessitating its removal from its case.

The connection between the stations was kept up partly by wires, partly by a cable laid along the ground.

Wires.—These were of copper, 1.6 mil. in diameter, weighing 22.5 kilog., and costing about 100 francs per kilom. This wire proved an excellent conductor, and, with care, could be used with intervals of 200 and 300 m., or even more, between the supports.

Cables.—Several kinds were tried. In the last experiments the cable was formed of a core of five annealed copper wires, bound round with white cotton thread, over which was a coating of gutta-percha, and then a layer of oakum, the whole being bound round twice with cotton tape steeped in vulcanized india-rubber. It weighed 35 kilog., and cost 320 francs per kilom. It was perfectly insulated, and a good conductor. When laid along the ground it suffered little from wheels and the feet of horses passing and repassing over it. But it had serious defects. It was rather too large in its diameter, and very weak, stretching sufficiently to injure the core with a strain of 30 kilog., and breaking with one of 40 kilog. The wires of the core were so fine as to be frequently cut through in removing the covering for the purpose of splicing.

Supports.—The wires were supported on light staves called lances, 3 m. 80 c. in length, 200 of which made a military wagon load. They were sunk 12 in. in the ground, and weighed up with wooden pickets. Where the line made an angle, the lances were strengthened with guy-ropes, known as haubans, attached to iron pickets. The lances could be lengthened by attaching two or more, end to end, by means of rings called anneaux de rallonge, fitted with clump screws.

Insulators.—With spires of india-rubber made hollow so as to fit over the end of the lances, and surmounted by a small cylinder of the same material. The wires were attached to the insulators by a couple of turns.

Iron cramps were also supplied which could be driven into the ground, or into the walls and trees *en route* to support the cable when used in place of wires.

For the transport of this *materiel* four-horse tilted wagons were provided of three descriptions. Each wagon was supplied with lamps arranged for external or internal use, and carried a distinguishing flag marked with a T in front. The draught in "marching order" is not stated, neither are the kinds of timber used in their construction of the wagons specified. The voiture poste, or traveling telegraph office, was in two compartments—the front serving as an office, the rear containing reels for the wire or cable. On the left of the front compartment (which was furnished with small windows) was a table, to the top of which was screwed the case containing the telegraph. On the right was a seat for two operators, under which were placed the batteries. The "earth connexion" was maintained by means of a wire communicating with the iron axle-tree, which in its turn was connected by means of the brass axle-tree boxes, and a metal rod running along one of the spokes with the tyre of the wheel. The connexion was thus independent of the movements of the vehicle. Where a good "earth" could not be found the wheels were wetted from time to time, or the wire was detached from the axle-tree, and tilted to a hollow iron picket provided with holes and filled with water,* which was driven into the ground under the wagon. This could of course be done only during a halt.

The other wire was connected with the metal work supporting the reels, and through it with the iron cheeks of the latter, against which one end of the wire or cable was clamped. These two wires, like those connecting the telegraph with the batteries, were of copper coated with gutta-percha. The contact was secured each time the telegraph was put in work, by means of small brass button-headed screws, known as bornes, serrés fils, and serrées lames.

The sides of the front compartment were fitted up with drawers and pockets for carriage of spare stores, etc. The hind compartment held eight reels, four on either side. The cores, cheeks and axles of these reels were of iron, the other parts of wood. The axles revolved in sockets fixed on two iron rails running along the sides of the compartment, and known as chemins de fer. Some ingenious arrangements were provided for regulating the motion of the reels, and protecting the hands of the men working them.

Each reel carried 5 kilom. (130 kilog.) of wire if required. But as 90 kilog. had been found to be about the maximum weight of a reel to be perfectly manageable, it was considered preferable to have 2 to 3 kilom. only on each, or 1 kilom. of the cable above described. The total interior length of the voiture poste was 3 m. 20 c.

The chariot poste-bobine, or wire wagon, was similar in exterior to the above, but somewhat longer, the interior length being 3 m. 90 c. It carried twelve reels, six on a side, each having 3 kilom. of wire. The lances, thirty or forty in number, were racked longitudinally between the two rows of reels. Each wire wagon carried also a supply of pickets, wood and iron, insulators, ropes, &c., &c.

One voiture poste with its accompanying chariot poste-bobine was estimated to carry a length of wire equivalent to an average day's march of 20 kilom. (or $12\frac{1}{2}$ miles.) The poste centrale resembled the voiture poste without the reels, the whole interior being fitted up as a telegraph office. Two ateliers, or squads, each consisting of one sergeant, two corporals, and twelve soldiers —exclusive of drivers, buglers, &c.—were told off to each voiture poste with its accompanying wire wagon.

In addition to the arrangements above described, an equipment for mountain service was provided on the following plan—this was called the poste roulante:

A mule or pack-horse carried two panniers, one on each side, one holding the telegraph apparatus, the other the battery, the weight of the two being equal; each case being also provided with drawers for the carriage of insulators, cramps, &c., so arranged as to allow of their being opened without removing the panniers from the mule's back. Across the top was packed a small light square tent, to serve as an office, and a tripod table for the apparatus, an iron picket for "earth connexion," and a bag of tools. A second mule or horse carried two reels with their supply of wire, slung pannierwise across a pack-saddle by means of chains.

* A supply of water was carried in a small gutta-percha cistern fitted in rear of each wagon.

As the unwinding of the reels on the mule's back would not only alarm the animal, but also disturb the balance of the load, a small wheelbarrow was also provided, light enough to be lifted up in the hands if necessary, and fitted to receive one pair of reels. The mallet required for driving the picket could be used as a handle, so as to enable a man to push the contrivance before him without stooping.

This little barrow often proved of great service, even with the wagons, in passing over broken ground. In crossing streams, too, it could be placed in the stern of the boat, thus greatly facilitating the "paying out" of the cable.

The operation of laying down the line was conducted as follows: A wire-wagon, followed by its voiture poste, marched first, both wagons halting from time to time to allow of the working party keeping a little ahead of them. The signals for advancing and halting were given with a whistle. The working party usually consisted of one atelier (15 men) divided into three subdivisions, and without arms or packs.

The sergeant marched at the head, marking out the line foot by foot. The first subdivision followed, digging the holes for the lances usually at 50 to 60 m. apart, or when cable was used, digging the little trenches to receive the latter at points where roads had to be crossed, fixing the cramps for its support at distances varying in accordance with the nature of the ground, &c. The second party unwound the wire or cable, making the splices and joints. The third then attached the wire to the lances fixing the latter; or laid out the cable, filling in the trenches where such were made for it, and finishing the line generally.

The work was very arduous. The average rate obtained on the most favorable ground was two kilom. the hour with suspended wires, and five kilom. with cable. In passing villages, &c., double the above time proved requisite.

For taking up the line, five or six men marching in inverse order were sufficient. The rapidity with which this manœuvre was executed equaled and sometimes exceeded that of ordinary route marching.

In joining the lengths of cable, the covering was first removed and an elastic india-rubber tube slipped over one length, the wires were then spliced and the india-rubber tube drawn over the joint and secured by tying down the ends firmly with twine. This was found to answer perfectly; but as the tying process took up some little time, small cylinders were sometimes substituted for the india-rubber tube. These contained two india-rubber discs having holes in them for the passage of the cable, and hollow screws at each end working against them. The screws were made hollow so as to allow of the passage of the cable through them. The splice was made in the ordinary way, the tube drawn over the joint and the discs compressed round the cable by the action of the screws. A joint could be thus made in thirty seconds. It was found, however, that the vibration of the cable loosened the screws and allowed water to leak into the joints.

The experiments at Chalons were conducted by a corps formed provisionally of detachments of the different regiments in the camp, under the superintendence of some officers of the Etat Major, assisted by some *employés* of the Administration des Télégraphes. They were of various kinds. On one occasion when a series of manœuvres were executed in presence of the Emperor, parties of the telegraph corps accompanied each division. Communications were kept up between the divisions and the head-quarters, and with the telegraph station at Mourmelon through which despatches were transmitted to Paris. On another occasion a party of the corps, with a voiture poste and wire-wagon, accompanied a cavalry reconnaissance to a distance of 8 kilom. from the camp. They laid down a line of telegraph, transmitted several reports to camp, and took up the line again in time to re-enter the camp with the cavalry.

The crowning experiment was made on 30th July. A party of the telegraph corps, consisting of four officers, two civil *employés*, 70 men, five wagons, including a forage cart with the baggage, and 30 horses and mules, marched from the camp at midnight with provisions for two days. A line of wire, 7 or 8 kilom. in length, had been established the evening before. The night was very dark. The party arrived at its destination at 1 A. M., and immediately commenced the prolongation of the above line, with the aid of lanterns. By 6 A.M., 24 kilom. of line had been completed, and guards established along it. The party bivouacked at Perzy. The line remained in use 36 hours. At 5 A. M., on 1st August, they started again for Chalons, and re-entered the camp at 10.30 A. M., having brought in the whole of the line of telegraph.

These experiments were considered highly satisfactory. We learn, however, that the Imperial Government has not considered it expedient to establish a separate corps for telegraphic purposes at present; the *materiel* has accordingly been made over to a company of the Corps du Génie, by whom the duties are in future to be performed.

WHITE PIG-IRON IN THE BESSEMER PROCESS.

By Dr. Adolph Schmidt.

It has been found by numerous experiments, made and repeated in all iron and steel making countries, that white or even mottled pig-iron cannot be worked to advantage in the Bessemer converter. The most celebrated brands of Bessemer pig are gray and graphitic to such an extent as to be almost unfit for foundry purposes. When white or mottled iron is used in the Bessemer process, the first or slag-forming period, which with good working irons, lasts from nine to twelve minutes, passes over in five or six, and as the duration of the second and third periods is generally unchanged, the whole charge is thus shortened about five minutes. In the second or boiling period of the process, when the carbon is in full and rapid combustion, and a bright flame with sharp outlines is rushing through the mouth of the converter, white iron causes vehement eruptions, and thereby considerable losses of metal.

During the third or finishing period, the flame appears then mostly dull and pale, indicating a comparatively low temperature of the metal in the converter. The reaction of the recarburizer is slow and weak. The final product, though sometimes of a bright appearance in pouring, chills easily in contact with less hot objects. Parts of it stick to the interior walls of the converter, especially near its mouth, and a heavy scull in the ladle is unavoidable. It is evident that a favorable percentage of ingots cannot thus be obtained.

The product is, besides, not of a very good quality. Though the white iron may be good and pure, the Bessemer metal made from it shows frequently this peculiarity—that it can be worked perfectly well at a red heat or at a white heat, but that it cracks and even crumbles to pieces when hammered at an intermediate or yellow heat. This deterioration by a yellow heat goes in single instances so far as to make a bar, which is heated yellow, break off in being simply bent. This peculiarity, which no other but Bessemer metal ever shows, is often the consequence of a cold charge. It has been called "shortness" in Sweden and Austria, where it sometimes occurs with the best brands of iron. After the analogy of the word "red-shortness," which is in general use, "yellow-shortness" would perhaps be a more appropriate expression.

The effects above described are produced by most white or mottled pig-irons when subjected to the pneumatic process, the spiegeleisen not excepted.

The short duration of the charge, and the coldness of the product, leads us to suppose that a lack of carbon might be the cause of all this. If not only carbon is taken into consideration, but also silicon, sodium, potassium, aluminium and other ingredients which, at moderate temperatures, have more affinity for oxygen than carbonhas, this supposition appears to be well founded. For, though a good white iron contains generally nearly or quite as much carbon as a gray iron, the latter, however, being made at a higher temperature, always contains a much greater quantity of silicon and other matters which require a high temperature to be reduced, and the total percentage of carbon and silicon, etc., is always higher in a good gray iron than in a good white iron, provided that the latter has not been made white artificially by sudden cooling in water or in iron molds.

When an iron containing a considerable amount of silicon is worked in the Bessemer converter, four-fifths of the silicon and only one-third of the carbon are burnt during the first period, which takes over one-half of the time of the whole charge. It is seen, from this fact, that the greater part of the carbon is saved for the latter half of the charge, and can then exert its full heating power on the iron, the latter being heated up slowly and gradually by the previous combustion of the silicon. When, on the contrary, a pig-iron without silicon is converted, the carbon enters very soon into full combustion. The difference between the temperature of the gases produced and that of the molten iron is then so great, that the rapidly escaping gases carry off uselessly a great quantity of heat which otherwise might benefit the iron, and the greater part of the carbon is consumed before the time when the heat would be most required and most useful.

The heat produced by the burning silicon is also more fully utilized than that produced by the burning of the carbon, because the product of the combustion of silicon, viz: silicic acid is not gas, but a solid substance, and does not escape rapidly, but combines with the slag, and is thus retained in the converter, where it has ample opportunity to communicate its surplus heat to the metal.

It seems, therefore, that not exactly a lack of carbon alone, but that a lack of "fuel" in general, that is to say, too small an amount of all the substances which by their combustion produce the heat in the Bessemer process, is the real cause why white or mottled pig-iron cannot be worked to advantage. Guided probably by these considerations, Mr. Edward Stockher, general director of the Imperial Iron and Steel Works at Neuberg (Styria), has conceived the idea of adding fuel to the Bessemer charge in case the pig-iron should not be sufficiently gray to make a hot charge by itself. He proposed, and tried with success, blowing charcoal dust into the converter.

The first trials were made in 1867, and since that time charcoal has been used regularly in almost all the charges. At Neuberg, the pig-iron is generally run from the blast furnaces into the converter without being remelted. The iron must be highly graphitic to make hot Bessemer charges and to produce a good metal. To insure this desirable effect, independently of the unavoidable little irregularities in the blast furnace, a great amount of charcoal had to be used for the production of the pig-iron, and the furnaces had to be conducted with the utmost care. Since the introduction of Mr. Stockher's method of blowing charcoal dust into the converter, a saving of 22 cubic ft. of charcoal is effected per ton of iron without injuring the quantitative or qualitative results of the Bessemer process. A sample of the pig-iron is taken and inspected before each charge, and the less gray and graphitic it is found to be, the more charcoal dust is blown into the converter. When this operation is properly regulated and managed, the charcoal dust is burnt in the converter below the surface of the iron, and increases the heat to such an extent that excellent results are obtained from mottled pig-iron. The quantity of charcoal dust used varies from 60 to 200 lbs. in a charge of three tons.

According to a communication, received through the kindness of Mr. Edward Juchelka, at Neuberg, the apparatus used for the purpose consists of an upright wrought-iron cylinder, ending below in a narrow pipe by which it is connected with the main blast-pipe. The connecting pipe is provided with a cock. The required quantity of charcoal dust is put into the cylinder from above. The cock in the connecting pipe being closed, the cylinder is then shut tight at the top by an iron plate, which is screwed on to it. When the blast is let on and the converter is turned up, the cock is opened. The charcoal dust is then blown into the converter together with the air. This is distinctly noticed by the appearance of the flame. When, after some time, the blast ceases to carry charcoal dust into the converter, as it often happens, this is also noticed at once and easily helped. The blast valve is then shut down entirely for a few seconds. The pressure of the blast depending during this time on the pressure in the accumulator only, sinks rapidly from 20 lbs. down to 14 or even to 12 lbs., and when, after this, the valve is reopened, the blast continues to draw charcoal dust from the cylinder. As a general rule the pressure of the blast must be kept pretty high, because with a low pressure the charcoal is not burnt in the converter below the surface of the molten metal, but is carried through unchanged, and burns afterwards uselessly in the stack.

In November and December, 1868, some attempts were made at Neuberg to use graphite instead of charcoal dust, according to the suggestions of Mr. H. Brunner, teacher at the Leoben Mining School. As highly graphitic pig-irons work best in the Bessemer process, Mr. Brunner thought that graphite might be more effective than charcoal when blown through the iron. But this idea is based on the probably erroneous supposition that gray pig-iron, even when in a molten state, contains a considerable amount of carbon in the shape of graphite. However, all the well-known phenomena connected with the chilling of pig-iron, seem to prove that in gray pig-iron, when melted, nearly all the carbon is combined or dissolved, and that it is not present then in the shape of a solid graphite. When gray pig-iron is melted and poured into cold water, it appears white, because sufficient time is not left for the carbon to separate from the iron and to crystallize as graphite. The iron is then retained in about the same molecular condition and construction which it had in its fluid state.

A report on the experiments made with graphite, by Mr. J. Schmiedhammer, the chief engineer and technical manager of the Neuberg works, is published in "Oestr. Zeitschrift," 1869, No. 23. This report is the more interesting, as it compares the results obtained with graphite with those obtained by the use of charcoal dust.

Mr. Schmiedhammer reports as follows: "The experiments were made in the small converter, to get the charges as small as possible. The graphite used was of the best quality, and finely pulverized. In the first charge 50 lbs. of graphite were blown into the converter, that is, about one per cent of the pig-iron. In the three following trial charges, two, three, and four per cent of graphite were used. Immediately after the third, and again after the fourth trial charge with graphite, another charge was made with the same pig-iron, and under the same circumstances, except that charcoal dust was used instead of graphite. The pig-iron was taken from the available stock, and was melted with coke in a cupola furnace. The pigs were carefully selected and of uniform appearance. The iron was mottled and of such a composition that it became white when cast into iron molds.

The results of the six experimental charges (four with graphite and two with charcoal dust) are contained in the following table:

In comparing the results contained in the above table we are led to the following conclusions: Graphite, when blown into the converter, does not remedy to a lack of carbon in the pig-iron. The graphite seems to burn but incompletely, if it burns at all. This fact is also indicated by the flame, which has a more or less dull and cloudy appearance in proportion as graphite is used.

Graphite does not lengthen the first period of the process. This is, however, done by the charcoal dust, the use of which therefore counteracts the disposition of mottled pig-iron towards producing vehement discharges from the mouth of the vessel.

Graphite is not able to make a charge with mottled iron hot enough, not even when the iron is very hot in being run into the converter.

The product obtained with graphite has all the qualities of a metal resulting from a cold charge. It chills easily, and is short at a yellow heat. The slag is pasty and tough, and not very fluid. Great losses are caused by discharging and sculling.

With graphite the pressure of the blast has to be diminished considerably during the second period, to avoid too copious discharges. This is necessary but to a very small extent when charcoal dust is used.

The charges, Nos. 905 and 950, made with mottled iron and charcoal dust, were as regular and good as if gray iron had been used. The duration of the first period was

In charge 895, a small quantity of pig-iron was used for recarburizing, because the loss of metal from discharging was considerable.

In charges 949 and 950, a large quantity of pig-iron was used for recarburizing, with the intention to produce a harder grade of metal.

normal. The metal proved to be of good quality. The slag was very fluid."

From this report, and from the fact that Mr. Stockher's method is in continual and successful use at Neuberg, we may infer that to work mottled iron by the Bessemer process, fuel is required, and that this fuel must be such as to burn readily with air at a moderate temperature.

Some kind of gaseous fuel, for instance, ordinary illuminating gas, when used with the necessary precautions against explosion, would perhaps make it possible to convert even a white pig-iron to advantage into Bessemer metal. The economy of such a proceeding would depend on local circumstances.

MODERN ORDNANCE.

From the opening address of Sir WILLIAM G. ARMSTRONG before the Institute of Mechanical Engineers, at Newcastle.

When battles were fought hand to hand, war, so far as mechanics are concerned, was an affair of muscular force, and was in that form the most sanguinary, because combats were the most close. When other forces were called into play, inventive appliances became necessary, and these, as they have advanced, have more and more widened the distances separating combatants, and have thus operated to prevent that greater sacrifice of life which would otherwise have resulted from the employment of more destructive weapons. It is, therefore, not to be supposed that future wars will be rendered more murderous by the intervention of the engineer; on the contrary, we may fairly anticipate that the more the element of intelligence supersedes that of animal force in military struggles, the more will the barbarity of war be mitigated. Science naturally sides with civilization, and tends to establish a supremacy over barbarism, and we find this tendency, as in the case of the late Abyssinian war, not only giving overwhelming superiority to the cause of civilization, but deciding the issue with the least possible waste of life. But whatever our sentiments may be in regard to war, it would be absurd to contend that we ought to withhold from invention, when the object sought to be attained is the destruction of life and property. It is our province, as engineers, to make the forces of matter obedient to the will of man, and those who use the means we supply must be responsible for their legitimate application.

It will be in the recollection of the members of this institution who visited the Elswick works on the occasion of the last meeting at Newcastle, that two or three small breech-loading rifled guns were shown to them as novelties deserving their attention. Those guns had then very recently received the recognition of the British Government, and may be regarded as the small beginnings of a system of ordnance which has since attained a very extensive adoption in this and other countries. It was not until the principle of rifling was adopted for military firearms, that these weapons presented much scope for the mechanician's art, but the introduction of rifling, and the change in the form of the projectile from a sphere to a pointed cylinder, brought about a complication of new conditions which it has required years of research and experiment to meet and satisfy. Passing over the subject of rifled small arms, which of late has called forth a great amount of ingenuity and skill, I will speak of artillery, as being that division of gunnery with which I am personally connected.

The most important of all the considerations affecting modern artillery, is how to obtain the strongest possible tube with the least possible weight. Before I state my views as to the best mode of attaining this object, I must call attention to the conditions affecting the force to be resisted. When a charge of powder is fired in a gun, it is converted into gas at an exceedingly high temperature, and the pressure exerted is due, even in a greater degree, to the heat than to the quantity of gas produced. But the heat evolved is not wholly realized in augmentation of pressure, a considerable part of it being absorbed by the material of the gun. The heating of a gun by firing is an effect familiar to every one, and it affords an indication both of the quantity of heat abstracted from useful effect, and also the amazingly high temperature of the gas before it escapes from the gun. Fifty rounds fired in quick succession from a field-piece, will make it so hot that it cannot be touched. Since the flame is only in contact with the bore for about the 150th part of a second at each discharge, it follows that the aggregate duration of the flame contact by which the gun is thus heated in fifty rounds, only amounts to one-third of a second. The thin film of heated matter deposited on the surface of the bore at each discharge, contributes, in some measure, to this rise of temperature ; but we may regard the acquisition of heat from this source as fully neutralized by the cooling of the gun in the intervals occupied by loading. Thus, then, you will be able to appreciate both the intensity of the heat of the gas and the extent of the waste by absorption. In small guns the area of absorbing surface surrounding the charge is greater in relation to the mass of the charge, than it is in larger guns. Therefore, the waste caused by the heating of the gun is also relatively greater, and the gas never attains either the same heat or the same pressure in the smaller weapon as in the larger. But the greater heat attained in a large gun, adds to pressure not only directly, by expanding the gas, but indirectly, by accelerating the combustion of the powder. The powder must be regarded as fuel burning in a furnace, and the hotter the furnace is the quicker the fuel will burn. You will perceive, then, that the pressure of powder-gas per unit of surface is augmented by increasing the size of the gun, apart from all considerations regarding the projectile. But the pressure of the gas is further increased in large rifled guns by the great length of column represented by the projectiles. The resistance increases with the length of the projectile, and the pressure rises with the resistance. Augmentation of pressure is also caused by the rifled projectile having to acquire motion of rotation in addition to that of translation, though the increase of resistance, and of consequent pressure due to this cause, is not so considerable as is commonly supposed. For these various reasons, the introduction of the rifled principle, and the enormous increase of size demanded in modern ordnance, combine to intensify that pressure to a degree which taxes our utmost resources to control. The limit of the pressure actually reached in rifled guns of the largest size, when fired with English service powder, is not yet fully ascertained, but it is probably not less than 70,000 lbs. on the square inch.

Now comes the question of what construction is best adapted to resist so inordinate a strain. It was long since demonstrated by Professor Barlow, that a cylinder, to possess the greatest possible resistance to a bursting force, must, when out of action, have its interior in a state of compression, and its exterior in a state of tension. He further proved it to be necessary that the internal compression should diminish in an outward direction, and the external tension in an inward direction, up to an intermediate zone of neutrality. If these conditions were neglected, he showed that in a very thick cylinder, the material forming the interior portion would be stretched to the breaking point before the exterior portion acquired any considerable tension. The interior, therefore, would be overstrained, while the exterior would be understrained, and the aggregate resistance would necessarily be less than if all parts were doing full duty. This reasoning is the foundation of the argument in favor of built-up guns, in which every layer of the material is stretched upon the layers beneath, and the finished structure is in the condition of internal compression and external tension, demonstrated by Barlow to be that of greatest strength.

The Americans have endeavored, with partial success, to realize the advantage of this principle in cast-iron guns, by cooling the inside first, and allowing the external portion of the metal to shrink upon the hardened interior. The Rodman cast-iron gun is made upon this principle, and considering the nature of its material, has, in some examples at least, exhibited great power of resistance, though not sufficient to enable it to be used for heavy ordnance in the rifled form.

Where forged material is used for the fabrication of guns, this condition of outward tension and inward compression is unattainable except by the application of the material in successive layers, each stretched on those below. Considerations of economy or convenience may supervene to reduce the number of layers, as in the Fraser modification of coil-made guns ; but theoretical perfection will be most nearly reached in that gun which is composed of the greatest number of layers. To attempt to forge large guns in single blocks, is a direct violation of established theory, and the general failure which has attended such attempts, is a practical proof of the truth of the theory.

The next point to consider is the best kind of material for the fabrication of guns. In determining this question, the choice clearly lies between steel and wrought-iron. I say this with no disparagement of Major Palliser's system of adapting cast-iron smoothbore guns for rifling, by introducing a tube of coiled wrought-iron, but this method has, hitherto, only been applied with success to guns which, though formerly classified as heavy ordnance, are dwarfed by comparison with the ponderous guns of the present day.

For these we require the greatest strength we can attain, and cast-iron cannot possibly be regarded as so efficient for enveloping the internal tube as either wrought-iron or steel. In discussing which of these two materials is best, I shall be trespassing on controversial ground. Krupp and Whitworth, both great names in gunnery, though differing widely in their views on other points, agree in this, that steel is the right material for the entire gun. I, on the other hand, have always advocated wrought-iron in the form of welded coil for the chief mass of the gun, limiting the use of steel to the internal tube, which has abrasion to resist as well as tensile strain. The expression of my opinion upon this point may probably not be considered impartial, but I will nevertheless state the grounds upon which my preference of wrought-iron thus applied is based. It has been found both in Elswick and Woolwich guns, that whenever failure takes place, it almost invariably originates with that part which is made of steel. It is the steel tube which is nearly always the first to crack. So, also, when the vent-pieces or closing blocks of the breech-loading guns were made of steel, their fracture was alarmingly frequent, but since wrought-iron has been substituted, such occurrences are rare. The conclusion, therefore, at which I long since arrived, and which I still maintain, is that, although steel has much greater tensile strength than wrought-iron, it is less adapted to resist concussive strain.

This conclusion is in strict harmony with the fact that armor-plates made of steel have proved on every occasion of their trial, greatly inferior to plates of wrought-iron. The experiments which I made some years ago on the toughening of steel in large masses, by immersion, when heated, in oil, led me to expect that this fragility would be obviated by that process, and I felt sanguine that I should be able by such treatment to produce steel armor-plates of extraordinary resisting power. An armor-plate of steel was accordingly manufactured for experiment, and was tempered in a large bath of oil. Its quality was tried by test pieces cut off after tempering, and proved by tension and bending. The results showed a very high tensile strength, combined with so much toughness, that I was unable to match its bending power by any sample of iron I could compare with it. The plate was then sent to Portsmouth for trial, in the fullest confidence of its success, but two shots from a 68-pounder sufficed to break it in various directions, and it was justly pronounced a failure.

With these experiences before me, it is impossible that I can hold any other opinion than that the vibratory action attending excessive concussion is more dangerous to steel than iron, and were it not necessary to provide a harder and more homogeneous substance than wrought-iron for the surface of the bore, I should entirely discard the use of steel for the manufacture of ordnance. I do not mean to contend that very strong guns may not be made of steel, but I am convinced that failures will be more frequent, and, I may add, more disastrous, with steel than with iron, when the conditions of trial are the same. The want of uniformity in the quality of steel, continues to be another serious objection to its use; and, in addition to all these considerations, the element of cost is greatly in favor of the wrought-iron coil construction over every mode of manufacture in steel.

I will now offer a few remarks upon the interesting question of the probable future of guns. Upon the solution of this question depends the pattern of future ships, and also the policy of continuing or abandoning the struggle of armor-plates against guns. From my previous remarks on the increase of pressure with which we have had to contend as we have increased the size of our guns, it might be inferred that we were now nearly reaching a limit, beyond which the strength and endurance of our material would not enable us to pass. I am not prepared to say how far we could have advanced under the recently existing conditions; but certainly every increase of size would have been attended with increase of difficulty.

A new light, however, has just dawned upon the subject, which entirely alters the prospect. It has become apparent that the power which we have been using can be so modified as to produce the required effect, with greatly less strain upon the gun. It may appear paradoxical that there should be a limit to the theoretical advantage of increasing the initial pressure of the gas evolved in the gun, but the apparent anomaly will disappear on examination. The action of expanding gas in a gun is analogous to that of expanding steam in the cylinder of a steam engine, and we all know the advantage, in the case of steam, of having a high pressure to begin with, provided a steam jacket be used to maintain the material of the cylinder at a temperature equal to that of the entering steam. But in a gun we can have no provision analogous to the steam jacket, and it would appear that it is owing to the necessary absence of such a provision that there is a limit to the increase of initial pressure, beyond which no gain of propelling force is realized.

Perhaps I shall not be fully understood without explaining this curious and important subject in a more definite manner, and I will therefore endeavor to do so. The force exerted in a gun bears a certain relation to the heat evolved by the gasification of the charge. The greater the heat the greater the force, for heat is nothing more than unexpended force. I have already alluded to the loss of heat by transmission to the gun, and it is evident that this transmission must be greatest in amount when the heat of the gas is highest. By using a slower burning powder, less heat and pressure are evolved at first, and the waste of heat in the stage of initial pressure being less, more heat remains for expansive action. Hence the slower burning powder is weaker at first, but stronger afterwards, and although the total quantity of gas be only the same, and the pressure not so great at any point, yet the aggregate pressure throughout the bore may equal that of the more energetic and more dangerous powder. This would not be so if the gun, like the steam-jacketed cylinder, could be maintained at the maximum temperature of the elastic medium within. But in the case of the gun, that temperature would be far above the melting point of its own material.

It is only lately that attention has been strongly directed to the powder question in England. In Russia and Prussia, where great efforts have been made to obtain endurance with large rifled guns, powder similar in granulated form to that used in England, has long been wholly discarded and superseded by powder stamped into prismatic blocks, which burn more slowly; but although we have erred in using a powder for our new ordnance, so violent as to be justly designated "brutal," by the French, yet we have this satisfaction, that the ordeal which our guns have sustained with our severer powder, affords an assurance of strength which we could not have had if they had only withstood the mild description of powder with which alone continental guns have been successfully tried. Attention is now fully awakened to the subject, and a scientific military committee is conducting experiments upon the force of different descriptions of powder.

In these experiments the pressures exerted in every part of the gun are determined, by the use of an instrument of exquisite delicacy, invented by my friend and partner, Captain Noble. This instrument, which is a happy combination of mechanical and electrical action, indicates the velocity attained by the projectile at any number of points in the gun, and from these velocities the pressures are deduced by calculation. Thus a diagram of pressure can now be exhibited for gas in a gun, as well as for steam in a cylinder, and I think you will agree with me in regarding this result as no small triumph of mechanical science. The mitigation of initial pressure, which is now known to be compatible with the maintenance of efficiency, opens a new future for guns, and removes all doubt as to the practicability of increasing their size and power to an extent which it would be vain to follow on the side of the defense by increase in the thickness of armor.

No present armor-clad vessel is proof against present guns, and there is not the slightest probability that future armor will be proof against future guns. Ships of the Warrior class can already be pierced with shot or shell, fixed at considerable ranges, by even second-class guns, and the still stronger ships, now in course of construction, are pretty sure to be similarly overtaken in a very few years. Unless armor be invulnerable, it is of very doubtful advantage as a defense. It will, perhaps, prevent the entrance of shells, containing large bursting charges, but on the other hand the passage of a shot through the thick side of an armor-clad, carries with it a mass of fragments that would act with terrible effect upon the crew. If we cannot stop a shot, the next best thing is to facilitate its passage through.

Wooden ships are out of the question, because they are combustible, but we may have ships of iron without the armor. Whatever weight we carry as armor, we lose as armament, and if we lessen the offensive power of a ship, by loading her with armor, we ought to be very sure that the armor will realize its defensive purpose.

The efficiency of modern ordnance against armor-plate is dependent, not only on the power of the gun, but also upon the material and form of the projectile. Ordinary cast iron proved absolutely useless for projectiles to be used against thick armorplates, and until Major Palliser applied the process of chilling to the manufacture of cast-iron projectiles, there was every reason to believe that hardened steel was the only material that could be used for this purpose with effect. The process of chilling gives extreme hardness to cast-iron, but, in point of toughness, a chilled cast-iron shot is inferior to one of steel. Steel, however, though much less liable to break, is more easily crushed; and this brings me to notice a curious evidence of difference in the amount of the penetrative power lost by crushing and by breaking. A crushed projectile is always much less heated by the blow, but the fragments of a chilled projectile remain cool. Hence, we see that crushing detracts more from the power of a projectile than breaking, because the heat developed in a projectile by striking a plate, is a criterion of the amount of force expended upon the projectile, instead of the plate. We accordingly find that a Palliser shot breaking by impact, will nevertheless pierce more easily than a steel shot which remains whole, but yields to crushing.

As to the proper form of head to be given to the projectile for piercing armor, you will remember that a few years ago this question was hotly contested between the supporters of round heads and flat heads; but, as often happens in the case of human contentions, not limited to the sphere of mechanical engineering, both parties were afterwards proved to be wrong. When Major Palliser brought forward his chilled projectile, he advocated a pointed head, and with the new material he was found to be right. Major Palliser has competitors on the Continent, whose claims I cannot pretend to weigh, but in this country, at all events, he is entitled to the honor of improving both the material and the form of the projectile, thereby greatly increasing the penetrative power of our artillery, and, at the same time, effecting an enormous economy in the manufacture of projectiles.

The most legitimate use of instruments of war is for the purpose of home defense, and I, therefore, proceed with satisfaction to notice a class of inexpensive vessels requiring no armor, and adapted to render the heaviest artillery available for the protection of our shores and harbors. Until very recently, there seems to have been an impression that large guns required large vessels to carry them; but the fallacy of this idea has been practically shown by the proving barge of the Elswick works, which is a mere floating gun carriage. This little vessel, which is only sixty tons burden, is continually used, without difficulty, for the trial of twelve ton guns at sea, even when the swell is considerable. This proving barge was the origin of Mr. Rendell's idea of the now well known gunboat Staunch.* The Elswick barge has no steam power, and thus represents the minimum of size; but the Staunch is provided with steam power, both for propulsion by means of twin screws, and for working her twelve-ton gun. She is, therefore, somewhat larger than the Elswick barge, and yet so small as to be very inexpensive, and at the same time a very difficult mark to hit. To burden such a vessel with armor, would at once increase her size and her cost, thus rendering her more easy to hit, and more expensive to lose. A simple screen might, perhaps, be advantageously applied as a protection against shrapnel; but thick armor, if used at all, should be reserved for ocean ships. I have so recently published my views on the subject of this vessel, that I need not now repeat them further, merely observing that guns of the largest size now made, or ever likely to be made, may be mounted in vessels similar to the Staunch, without increasing their tonnage in more than a proportionate degree.

Another recent invention, highly favorable to defense, is the celebrated gun carriage of Captain Moncrieff. By the ingenious arrangement of the carriage, the recoil of the gun operates in a downward direction, and in descending it lifts a counterweight, which, when liberated, after loading, raises the gun again to the height necessary for firing over the edge of a parapet. By this mechanism, the gun is handled with almost perfect security to the men, and is itself exposed in the smallest possible degree, and only for a few seconds while being fired. No embrasures being required, the gun is not restricted in lateral range. This is the characteristic advantage of the barbette system of mounting guns, which has, however, the fatal objection of exposing both guns and gunners. Embrasures are always a source of trouble in fortifications. They not only

* The idea of floating, self-propelling gun carriages, was original with the late Edwin A. Stevens, one of the projectors of the "Stevens Battery," and the first practice in this direction was that of the Stevens gun boat "Naugatuck," during the late war.—Ed.

admit but guide projectiles into the fort at the very points where guns are placed. In iron defenses, the opening for the gun is even more objectionable. Not only does it weaken the whole structure, but it serves to break up cast-iron shot striking on the edge, and thus to occasion terrible destruction inside. I may state as a fact, communicated to me by a Brazilian officer, on whose testimony I rely implicitly, that in the late Paraguayan war, in which he was engaged, he saw whole gun crews swept away in the Brazilian iron-clads, by common cast-iron round shot, contemptible for piercing even the weakest armor, but which, striking the edge of the port, entered the ship in a torrent of fragments. The Moncrieff gun carriage gives great additional value to earthworks, and, in fact, may be used in mere pits which would be wholly invisible to an enemy. It would probably also prove to be available in combination with iron defenses, as a means of avoiding the objection of port-holes, and it will have the effect of placing muzzle-loading guns on a par with breech-loaders in regard to security and ease of loading. Captain Moncrieff's invention will play a very important part in defensive operations, and will greatly reduce the expense of fortifications.

Many other instances may be cited in illustration of the tendency of mechanical progress to favor defense. Thus the increasing size of guns renders them difficult to transport for offensive use abroad, but creates no impediment to their defensive application at home. Or, if we look to the nautical side of the subject, we see that the conditions sought to be attained in war-ships for aggressive action involve enormous cost, and that the great size of these vessels makes them favorable targets for the fire of opposing artillery. On the other hand, the vessels required for coast and harbor defense are of cheap construction, and their small size and facility of movement give them the advantage of being difficult to hit. The Moncrieff carriage is applicable almost exclusively to defensive purposes; and the same may be said of torpedoes, which, by many ingenious contrivances, have recently been rendered most formidable obstacles to naval attacks upon seaports. The tendency, therefore, of mechanical invention, as applied to war, is to discourage aggression, and thus to maintain peace. We may, consequently, hope that it will hasten the arrival of a period when civilized nations will abandon the arbitrament of arms, and settle their differences by rational and peaceable methods. But, while I defend the mechanical branch of military science from all imputation of serving the cause of war, I do not forget that it is to the civil branch of mechanical engineering that the honor of promoting the friendship of nations especially belongs. It is by the facilities it gives to intercourse and exchange, and by the reciprocal benefits which flow therefrom, that it teaches men how much they have to gain by peace and lose by war.

The Avondale Disaster.—We have in this country long been spared the frequent and ghastly disasters that characterize British mining. Even the few catastrophies that have occurred here, are attributable to carelessness and neglect rather than to the presence of noxious and inflammable gases. It would appear that human ingenuity could hardly have devised a more certain man-trap than the Avondale mine. But whatever the causes of these terrible sacrifices may be, *mining by machinery* will now begin to have the significance and attention here that it is receiving abroad. The breaking down, moving and manipulating of coal by inanimate power, with only the supervision of a few men, will at once and greatly decrease the risks to human life and the cost of getting coal—and humanity has little to hope for if economy and safety do not go hand in hand.

THE ELLERSHAUSEN PROCESS.

We publish, herewith, a table of the results of several single heats made by this process at the Bessemer Steel Works, Troy, and also the results of five weeks' continuous working at the establishment of Messrs. Shoenberger & Co., at Pittsburg.

The mixing of the ore with the melted pig-iron, in the Troy experiment, was thorough, and the subsequent operations in the puddling furnace were very carefully performed. The results, however, are not uniform, and do not, as a rule, show the improvement in the quality of the product observed elsewhere. It is now evident that the Troy experiments were not sufficiently extended to give a fair average result. It appears from these experiments that some irons are better adapted to this process than others; also that the ore from which the pig-iron is made is not the best ore to mix with the same pig-iron, to convert it into a pig-bloom.

Experiments made by the Ellershausen Process, at the Bessemer Steel Works and at the Rensselaer Iron Works, Troy, N. Y., April, 1869.

Dakin Hematite Ore.

Sesquioxide of iron	62.94
Protoxide of manganese	.40
Silica	26.32
Water	10.65

Port Henry No. 21 Ore—Magnetite.

Sesquioxide of iron	60.39
Protoxide of iron	27.06
Titanic acid	1.30
Silicic acid	5.38
Magnesia	2.36
Alumina	2.80

The results of five weeks' working at Messrs. Shoenberger & Co.'s, are based on the amount of ore used in the blast-furnace, also the amount of pig metal and of pig-bloom (conglomorate of ore and partially decarburized pig-iron, as obtained by the Ellershausen process), and the average loss on the pig bloom.

During this time all the cinder from the Ellershausen process was used in another blast-furnace where they were making white iron for a rail mill in Chicago.

Ore used.		lbs.
Mannora	at 50 per cent,	2,286,502
Iron Mountain	at 66 "	1,299,789
Sterling	at 50 "	613,307
Lake Superior	at 62 "	498,882
Containing iron		2.617,540

Iron produced.	lbs.
Pig metal	739,200
Pig bloom	2,452,800
	3,192,000

Loss on pig bloom in furnace 24 per cent (average), the bloom containing, according to the calculation of Messrs. Shoenberger & Co., about 27 per cent of ore (Lake Champlain).

Supposing even that the pig metal, if worked into the Ellershausen bloom, had yielded only its own weight in muck-bar, instead of gaining 3 per cent, then we have

	lbs.
Iron from pig metal	739,200
" pig bloom	1,849,600
Total amount of iron	2,588,800

This would show only a loss of a little above one per cent over the amount of iron contained in the ore as found by analyses.

The loss in puddling their pig, Messrs. Shoenberger have found to average 8 per cent.

It is a fact that Messrs. Shoenberger & Co. have not heretofore been able to make horse-shoes from their own puddled iron, but were always compelled to buy good scrap iron. Now they are making all their horse-shoes from the Ellershausen iron, the *horse-shoe billet* being rolled directly from the muck-bar.

The following data relating to the Ellershausen process are from Messrs. Shoenberger & Co.'s books:

In *the puddling process* the production of a single puddling furnace is about 2,600 lbs. per day.

To fix the bed of furnace takes from 100 to 150 lbs. of scrap iron.

To fix the bed of furnace takes from 200 lbs. of ore.

In the *Ellershausen process* the production per day, in single furnace, is 4,000 lbs.

To fix the furnace-bed they have used only 50 lbs. of ore per day, and *no scrap.*

Working in a large furnace—three men to the furnace—the yield per shift has been for months 6,300 lbs., consuming only 70 bushels of bituminous coal, while in puddling they use 47 bushels of coal per ton of muck-bar.

Table of Analyses.

1 Pig metal from Messrs. Shoenberger & Co., gray.
2. Pig metal from Messrs. Shoenberger & Co., white (only with reference to sulphur—was made from ore containing considerable am't of pyrites.
3. Slag from puddling process.
4. Slag from Ellershausen process.

The ore used for mixing in the Ellershausen process was a brown hematite, containing .21 phosphoric acid, 63.00 peroxide of iron, 13.00 water, balance almost exclusively silica and alumina.

In the iron of Lyon, Shorb & Co., from cold blast charcoal iron, there is no perceptible difference between the puddled and the Ellershausen iron, as far as the analysis goes. Mr. William M. Lyon considers the Ellershausen iron supperior to the puddled iron when brought to practical test.

In the experiments of Messrs. Shoenberger & Co., it has been shown that the sulphur is far more thoroughly eliminated by the Ellershausen than by the puddling process.

We shall give, in a future number, the results of the Ellershausen process as tried on a still larger scale, during several months regular working.

PILE-DRIVING BY GUNPOWDER.

From "Engineering."

Considerable attention has lately been paid in America to the ingenious method of driving piles by the explosion of gunpowder recently introduced by Mr. Thomas Shaw, of Philadelphia, and we think that Mr. Shaw's system is likely to be regarded with equal interest on this side of the Atlantic. Mr. Shaw's "gunpowder pile-driver" as it has been named, consists merely of an ordinary pile-driving engine, having a ram provided with two plungers projecting, the one from its upper, and the other from its lower end, and fitted, moreover, with an arrangement for retaining the ram at any desired height. On the top of the pile to be driven is placed a casting, or cylinder, hollowed on the under side to fit the head of the pile, and having bored from its upper side a hole, into which the lower plunger of the ram fits. In this hole is placed a small charge of gunpowder, and the ram, having been raised a few feet, is let fall, when the lower plunger, entering the hole in the cap-piece, compresses and heats the air, which ignites the powder, thus causing the ram to be thrown up again, ready for another blow, and the cap-piece with the pile to be forced downwards.

The plunger at the top of the ram is for the purpose of entering into an air cylinder at the top of the frame, and thus forming an air buffer in the event of the ram being thrown up too high. This upper air cylinder is also useful when there is but little space available for striking a blow, as, in such cases, by hauling up the ram until the upper plunger is forced into the air cylinder, the downward stroke of the ram is accelerated.

So far the action of the apparatus is simple enough, and will be readily understood; but the results obtained with it are difficult to account for satisfactorily. Inasmuch as in regular working the ram is thrown up again to its starting point, it is evident that any work given out by it during its downward stroke must be re-absorbed by it during its upward stroke, and, therefore, that none of the work generated by the fall of the ram can be considered to be available for driving the pile. This driving action must therefore be performed by the power generated by the explosion of the powder, and it is the amount of effective work thus done by the powder which appears to us to be the most remarkable point in the whole affair. Thus, in the case of a model apparatus, lately exhibited by Mr. Shaw at a meeting of the Franklin Institute, the ram, with its plungers, weighed 73 lbs., and had a fall of 20 ft. When no powder was used, a pile, placed under this ram, was driven $\frac{1}{4}$ in. at each blow; but when a charge of 14 grains of white gunpowder (composed of chlorate of potash, ferrocyanide of potassium, and sugar) was employed, the distance which the pile was driven at each stroke was augmented to 2 in., or eight times its former amount. Now, if in this case we were to consider the power expended upon the pile to be in proportion to the distance which the latter is driven, we shall have the explosion of 14 grains of powder generating $73 \times 20 \times 8 = 11{,}680$ foot-pounds of work, or, as 14 grains are equal to $\frac{1}{500}$ lbs., there would be $11{,}680 \times 500 = 5{,}840{,}000$ ft.-lbs. of work developed by the explosion of 1 lb. of powder! Inasmuch, however, as a pound of ordinary powder, burnt in a gun, only developes, on an average, about 180,000 foot-pounds of work, we cannot think—even allowing for the white gunpowder being more powerful than the ordinary kind—that the power developed by the explosion of the powder in Mr. Shaw's pile-driver is anything like that above mentioned; and we are, therefore, led to believe that the efficiency of the apparatus lies more in the peculiar character of the thrust transferred to the pile than to any vast amount of power generated. In other words, it appears to us that in the gunpowder pile-driver a greater proportion of the driving power is turned to useful account than when the ordinary falling monkey is used, and this view of the case is borne out by the fact that with Mr. Shaw's apparatus no injury is done to the head of the pile itself. In the case we have just been considering, the ram was a light one, and its fall great, and these circumstances may at first sight appear to have contributed to the great comparative success of the apparatus when used with powder; but a reference to the report of Mr. Shaw's pile-driver, recently made by Chief-Engineer W. W. W. Wood, U. S. N., will show that, even with a heavy ram and short stroke, the advantages gained by the use of the gunpowder were equally great.

That Mr. Shaw's apparatus forms a very efficient pile-driving engine, Capt. Wood's report, and other information which we have received from reliable private sources, leave us no reason to doubt; whether, however, it is an economical one we have as yet not sufficient data to enable us to determine. In Captain Wood's report, the quantity of powder used is unfortunately not given, neither does the report afford any information concerning the number of men required to work the machine when in regular action. It must be remembered that in a well-arranged steam pile-driver the engine not only serves for working the ram, but also for lifting the piles into place, traversing the machine as required, and doing other work which, if it is to be done economically, must be performed by steam power in the case of Mr. Shaw's pile-driver also; and the question then arises whether, if an engine and boiler have to be provided, it is not better to employ them for doing all the work that has to be done. As regards the comparative cost of developing power by the combustion of coal under a steam boiler, and by the explosion of gunpowder, there can be little difference of opinion, as a pound of coal burnt under the boiler of a steam pile-driver will, on an average, allowing for all losses, produce about the same number of foot-pounds of effective work as a pound of ordinary gunpowder burnt in the chamber of a piece of ordnance, while the cost of the coal will in most cases only be about one-fiftieth of that of the powder. Even supposing the powder to have the vastly increased efficiency estimated from the experiments at the Franklin Institute above mentioned, the cost of generating a certain number of foot-pounds of work would still be in favor of the coal, and it remains to be proved whether in actual working Mr. Shaw's apparatus gives, from its handiness and rapidity of action, results which compensate for this increased cost of generating the power.

Whether Mr. Shaw's gunpowder pile-driver will be able to compete successfully with steam pile-drivers or not, it will undoubtedly render important services in situations where hand-worked machines have hitherto only been available; and in any case its action is in many respects so peculiar, that we feel sure that its further trials will be watched with interest by all who have had their attention directed to this subject.

ICE-MACHINES AND REFRIGERATORS.

From "The Engineering & Mining Journal."

For a century or more the great problem of converting heat into power was being solved, or, in other words, the steam-engine was being brought into existence. It advanced through various stages, and appears now to have attained, perhaps if not its full growth, at least a very high degree of development. At present another problem is being solved—namely, to convert power into cold; in other words, to construct machines to make ice, or produce cooling by means of the application of power; and as the cheapest power we possess is steam power, this is almost exclusively used, when we have the problem to produce cold by mechanical means.

The production of heat by mechanical means is very ancient. From time immemorial, the friction of two rubbing surfaces, such as a grooved board and a stick, has been used by savage races to produce fire; and the heating of the axle-trees of wagons and machinery by friction was observed centuries ago. Comparatively speaking, the practice and successful application of these phenomena have been carried out only recently. In a few factories in Germany, where there was a surplus of water-power, an arrangement was made for producing friction between two cast-iron surfaces, which became heated to such a degree that enough caloric was produced to perform the function of a heating apparatus for various rooms; while Beaumont, in 1856, constructed a heating arrangement driven by power, where the heat was produced by the friction of a very elongated cone of soft meterial, well oiled, and which was placed in a hollow metallic cone,* in which it fitted exactly. Upon being rapidly revolved, a perfectly noiseless friction was the result, producing the full equivalent of heat, as determined by Meyer, Joule, Grove, etc., and to which we have often referred before, namely: one unit of heat for every 772 foot-pounds power employed. The specific heat of one pound of water, being nearly equal to that of 50 cubic feet of air, every 772 foot-pounds will heat 50 cubic feet of air 1 deg., and 120×772, or 92,600 foot-pounds, will heat 120×50, or 6,000 cubic feet of air, 1 deg. If we spend this power every minute, we will have nearly 3-horse-power, as each horse-power is 33,000 foot-pounds per minute. Three horse-power properly employed will therefore heat a space of 6,000 cubic feet (the contents of a common passenger railroad-car) 1 deg. every minute. But as three-horse power cannot be obtained from a locomotive, by a consumption of coal of less than 30 lbs. per hour, it is seen at once that it would not be an economic operation, as so slight a calorific effect may be easily obtained from a common stove, with a consumption of less than one-tenth the above, two to three pounds of coal per hour; which is the average amount burnt in a stove of moderate size, and heats a room of the above dimensions sufficiently, even in the coldest season.

One of the most remarkable facts in connection with the transformation of power into heat, is the perfect uniformity of result, whatever be the means employed to accomplish this transformation. It may be friction of solids, of solids on liquids or gases, through agitating them by means of fan-wheels or other means, compression of gases, magnetic attractions, or by retarding revolving wheels. In short, there may be any means whatever employed to retard or destroy power or motion, we will always have the uniform result; that for every 772 foot-pounds apparently destroyed, one unit of heat will have been obtained—the only condition being precaution not to lose part of the heat thus obtained, nor to consume part

* For description of this apparatus, see *Génie Industriel*, Paris, 1856, page 18.

of the power employed in some other manner. By observing these conditions, different experimenters, employing a variety of means, have obtained such uniform results, that the number obtained, 772, representing the equivalent of heat and power, is one of the most securely established in the whole field of physical sciences.

When converting heat into power, by means of the steam-engine, the results are quite different, and the most enormous discrepancies appear, one machine producing nearly 110 foot-pounds per unit of heat, another 70, another 50, and another only 35 or 40—these numbers being respectively about 1-7th, 10th, 15th, and 20th of 772. It is thus seen that steam-engines produce only small portions of the theoretical amount, and are subject to a loss, ranging from 86 to 95 per cent of what we are some day entitled to expect.*

Referring to the subject mentioned in the opening of this article, the conversion of power into cold, the following question naturally presents itself: Is this conversion practically accomplished without great loss, and with tolerably uniform results, as in the case of the conversion of power into heat? Or is it subjected to the great loss of 86 to 95 per cent, as is the case where heat is converted into power by the intervention of the steam-engine? In answer to this question, we will state that in this case there is fortunately no such loss; when converting power into negative heat, we are able to abstract with a good ice-machine a unit of heat for every 772 foot-pounds of power employed; or 170 units for 170×772, or nearly 132,000 foot-pounds. If we expend the last number of foot-pounds per minute, we spend four-horse powers, and therefore theoretically four-horse power must produce a cooling effect of 170 units of heat per minute. As one pound of water of 62 degrees requires 30 degrees cooling to bring it to 32 degrees, and the abstraction of 140 units of latent heat, 170 units of heat abstracted from one pound of water at 62 degress will change it into ice of 32 degrees; and thus an expenditure of four-horse power must be able to freeze every minute one pound of water of 62 degrees—that is, sixty pounds per hour; and 40-horse power will freeze 600 pounds per hour, or 6,000 pounds per day of ten working hours.

This estimate, which gives the maximum amount of ice which can be produced by a given power, shows at the same time that the reason why artificially obtained ice can compete with natural ice, is, that steam power is so cheap. It has been suggested to make small machines, in which, by the labor of a man, ice, or at least cooling, could be produced, and such machines have actually been made, but only with doubtful success. This becomes clear when we consider that one-man power being only the 32d part of four-horse power, one man could freeze only the 32d part of a pound of water, one-half ounce per minute, or one pound in 32 minutes; this would be the maximum attainable, and that by hard labor, the most perfect arrangement, precaution against loss of power, absorption of heat, etc., all more difficult to obtain on a small than on a large scale. We are compelled to come to the conclusion that the system of refrigeration by means of power is only applicable on a large scale where steam or water power is available. To use the labor of a man to produce cooling by this system, is more expensive, as would be that of animals, in comparison to the employment of steam or water power.

If we estimate the amount of coal necessary to produce the result calculated above—namely, the production of 6,000 lbs. of ice per day by a steam-engine of 40-horse power—we find that, as a horse-power requires in an economical stationary boiler and engine 20 pounds of coal per hour, the 40-horse power will consume per day of 10 working hours 800 pounds of coal. The consumption of this 800 pounds of coal producing 6,000 pounds of ice, gives $7\frac{1}{2}$ pounds of ice for every pound of coal, or $7\frac{1}{2}$ tons of ice for every ton of coal on the supposition that each horse-power consumes two pounds of coal per hour. As, however, in the most economical boilers, a horse-power may be produced by the consumption of less coal, it is clear that it becomes possible to obtain more ice per ton of coal, which quantity can be further increased by future improvements in the steam-engine.

Having thus estimated what we may expect theoretically, let us investigate in how far the practical results obtained agree with these estimates.

In the first ice-machines, built on this principle, some ten years ago, one or two tons of ice were obtained by the use of one ton of coal, and it was at that time considered a great attainment that actually more ice was

* Readers desirous for details in this matter, are referred to the "Journal of Mining" for 1869.

turned out than coal consumed. Very soon it was claimed that, by means of the *ether-machine*, three tons of ice were daily produced by the consumption of seven tons of coal per week; then the ammonia-machine made four to six tons of ice for every ton of coal, which production was gradually increased to eight and ten tons, while lately twelve tons have been claimed for every ton of coal consumed. An ice-machine made by Liebe, and used in England for cooling purposes in a large brewery, produced a cooling effect, which formerly, by means of ice, could only be obtained by the consumption of 14 tons of that bulky material, while the ice-machine of Dr. Vander Weyde, of this city, which is now being introduced in the United States, is, it is claimed, more economical, and will in its effect excel Liebe's when perfected and worked with superior boilers and engines.

In regard to the cost of the ice thus produced, which is the chief consideration, we may say, it consists of the first outlay, the fuel and the labor. Considering the outlay, an ice-machine with a steam-engine of 40-horse power and boiler, costs, say $5,000, interest of capital, wear and tear of machine, at 15 per cent, $15 per week; labor $18, coal $7, water nothing; total, $40 for 20 tons of ice, or $2 per ton, slightly less or more, according to economy and price of coal and labor.

It is very fortunate that ice-making or conversion of power into cold, is not subject to from 86 to 95 per cent of loss, which is the case, in the conversion of heat into power, in the steam-engine. If this was the case, the tenth or twentieth part only, of ice could be made, with the same amount of machinery, fuel and labor, as now, and the price would be at least $20 to $40 per ton, in place of $2. It is clear that in this case artificial ice could seldom compete with natural ice, which for that price could even be conveyed to the tropics. However inland in tropical climes, it commands often $100 and more per ton, if it is to be had at all, and in such exceptional circumstances, even very expensive methods of cooling may be taken advantage of.

FAGGOTED AXLES.—The Albany Iron Works are making hammered iron railroad axles of a very superior quality. We shall in due time give the particulars of some tests of these axles, under the blows of a drop.

POPPER'S ANTI-INCRUSTATOR FOR STEAM-BOILERS.

By Dr. EMIL TEIRICH.

Translated from "Polytechnic Journal."

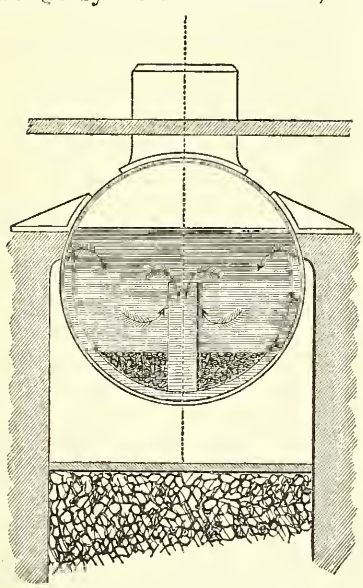
The incrustation of steam-boilers prevents, to a great extent, the transmission of the heat, and causes an early destruction of the boilers. Its removal from time to time is very expensive and inconvenient. The nature and quantity of this incrustation depends on the chemical composition of the feed-water.

When the water is first heated up to the boiling point, the bicarbonates which are dissolved in the water are decomposed, lose one half of their carbonic acid, are precipitated as insoluble carbonates, and produce the first deposit in the boiler. During the subsequent continuous evaporation of the water, the other compounds dissolved in it are concentrated and finally precipitated, when the limit of their solubility is reached. Another kind of deposit is thus produced, different from the first in its chemical composition. The great variety of chemical compounds dissolved in different feed-waters, is a proof that no general chemical means can exist, fit to prevent all incrustation from any water, and that every chemical remedy proclaimed as universal, is to be considered as an imposition. A certain substance cannot even prevent the formation of a certain kind of incrustation unless it is added before the water is brought into the boiler, thus precipitating and gathering the solid compounds outside of the boiler. A chemical analysis of the feed-water can alone give a correct idea of the value of one or other of these chemical remedies for special circumstances. Another method of relieving the feed-water of the greater part of dissolved matter, consists in pre-heating the water in a specially adapted vessel or apparatus, where it then deposits its carbonates. An excessive concentration of the other matters can be prevented by allowing a certain quantity of the contents of the boiler to run out every day, and by replacing it by fresh water.

A third kind of remedy against incrustation does not attempt to prevent the formation of deposits, but alters the nature of these deposits so that they do not adhere, by introducing such matters or arrangements that the deposits may be gathered upon them, and with which they can be quickly and easily removed. We reckon amongst these remedies: painting or covering of the interior of the boiler; mechanical admixtures to the water, which are said to rub and clean the interior boiler surface; the many existing mysterious substances, one of which, viz: Baker's anti-incrustator, has succeeded in acquiring a wide-spread but totally undeserved reputation.

An apparatus invented by Schmitz, and based on a new principle, was favorably received at the last Paris exhibition. By inserting curved wrought-iron plates into the boiler, Schmitz intended to create a regular circulation of the water, thereby to increase the evaporating power of the boiler, and to carry all precipitated matter to the upper surface of the inserted plates. This object is attained in a much more complete manner by Popper's anti-incrustator, and it has been shown most conspicuously by a trial made with it in November, 1868, in the machine shop of G. Sigl, in Vienna, (Austria.)

Popper's apparatus, a section of which is represented by the annexed sketch, consists



of long strips of sheet-iron about 12 in. wide, which are introduced through the manhole into the boiler, and there united so as to form a half-cylinder, placed parallel to the lower half of the boiler. Little projections attached to the outside of this half-cylinder prevent the latter from coming in direct contact with the boiler, but keep it at a certain distance above the interior boiler surface. This distance must be pretty short to make the apparatus very effective. In Sigl's boiler of $4\frac{1}{2}$ ft. diameter as used for the trial, this distance was $2\frac{1}{2}$ in. below the cylinder, and only $1\frac{1}{4}$ in. at the sides. So far, the arrangement is not very different from that of Schmitz. But Popper made a very important addition by inserting a row of vertical pipes of sheet-iron, five inches in diameter, and placed about 24 in. apart. These pipes are supported by the cylinder which has corresponding openings so as to effect a central communication between the water above and below the cylinder. The whole apparatus is set in loose, and kept in place by the weight of a thick layer of pebbles of egg size covering the lower part of the half cylinder. These pebbles, besides, perform the function of taking up all the deposits from the water.

The manner in which this apparatus acts, is indicated by the arrows in our engraving. The steam generated at the heating-surface, rises rapidly in the space between the boiler and the cylinder, creating a strong current, the most important factor of an economical steam-generator. But it does more. The vehemence of the evaporation and the rapidity of the current, prevent all precipitated matters from settling on the boiler plates and throw these matters, together with the water, several inches above the upper rim of the half-cylinder. As this rim is at a level with the lowest water-line, this arrangement is also a protection against the dangergerous consequences of sinking the water below that line. It could be seen distinctly in Sigl's trial-boiler that the water was thrown five or six inches above the normal water-level. It is even to be expected from this system that a continual washing and wetting of the interior boiler walls will take place so long as any notable quantity of water is left in the boiler.

The vertical pipes carry the water back to the heating-surface.

A certain part of the water is always quiet in the interstices between the big stones, where it deposits all the precipitates.

The apparatus is simple and cheap. The boiler in which Popper's apparatus was tried in Sigl's machine works in Vienna, presented a surprising appearance after an uninterrupted working period of three weeks. The interior of the boiler was so perfectly clean, that small impressions which had been made by the hammer during a previous cleaning operation, were yet to be seen distinctly. Also the outside of the half-cylinder was free from incrustation, and showed a metallic surface. The stones were covered with a thick crust of deposits, and so also was a part of the upper surface of the half-cylinder and of the vertical pipes.

To clean the boiler, nothing has to be done but to replace the stones by fresh ones. To do this easier and quicker, the stones will in future be laid into appropriate metallic troughs, in which they remain when in the boiler.

The work of the boiler was regular and undisturbed during the whole trial. The first heating-up was done quicker, the generation of steam was more rapid than usual. According to exact and careful observations, the priming was not more considerable than before. The consumption of coal was very low. As, however, no exact notes were taken about this, the economy of fuel effected by the apparatus could not be calculated for this trial.

Experiments on the applicability of Popper's system on Cornish ship and locomotive-boilers are in preparation, and will doubtless prove as successful as the above.

S.

HISTORY OF WATT'S STEAM ENGINE.

From Sir Wm. G. Armstrong's Inaugural Address before the Institution of Mechanical Engineers, at Newcastle.

This year is the centenary of the steam engine of Watt; and I am glad that it has fallen to the lot of Newcastle to receive, on so auspicious an occasion, a society which must regard Watt, more than any other man, as the father of their calling. First, then, I shall discharge my duty as your president, by paying a tribute of respect to the memory of the illustrious man who, in the corresponding year of the last century, completed and set to work the greatest of mechanical inventions.

In 1765, the authorities of Glasgow College, little thinking of the momentous step they were taking, intrusted a model of a Newcomen engine to James Watt, a maker of mathematical instruments, for repair. The sagacity of Watt enabled him, by an inspection of the model, to detect a radical defect in the principle of the engine. He saw that the condensation effected within the cylinder reduced its temperature, and rendered restoration of the wasted heat necessary at every stroke. He perceived that the steam ought to act in a vessel always hot, and be condensed in a vessel always cold. He thus conceived the idea of separate condensation. With a quiet tenacity of purpose he set to work, under great disadvantages, to realize his idea of a more economical steam engine. His design was soon matured, but the difficulty of execution long remained a barrier to practical success. In the Newcomen engine, the weight of the atmosphere, acting against a vacuum, was the moving power, and leakage of air past the piston was prevented by water resting on the upper side. An unbored cylinder, made in separate parts, sufficed for this arrangement; but in Watt's design steam instead of air acted on the piston. A water packing was inapplicable, and leakage could only be prevented by the more accurate fit of the piston in the cylinder. A moderately steam-tight cylinder and piston were, however, more than the workshops of the day could produce, and we read of his vain attempts to correct, by pasteboard and cork, inaccuracies of workmanship, such as in our time has no existence.

With ailing health, narrow pecuniary means, and a temperament inclining to despondency, he was, in many respects, unfitted for a struggle with difficulty; but he was a man whose mind was taken captive by an idea, and he could not help persevering. His attractive character and fine intellect had attached to him many valuable friends, superior in station to himself, and his letters to some of those friends, written during his struggles, exhibit at once his severe discouragement and his irresistible impulse to proceed.

In 1768, he had succeeded in producing a condenser with its necessary appendage of an air-pump; but it was not until the following year, 1769—exactly a century ago—that his first complete steam-engine was finished and put in motion. The first trial was made by Watt in a secluded glen, behind the house of his friend, Dr. Roebuck, near Linlithgow. The engine was not a mere working model, but a machine of considerable power. It had a cylinder of 18 in. in diameter, and a stroke of 5 ft.; but the cylinder and piston, which were described as the best the Carron Ironworks could produce, were still so inaccurately made as to defeat, in a great measure, the anticipated success. The engine, however, afforded a practical demonstration of the value of the invention sufficient to lead eventually to the happy alliance of the capital of Boulton with the genius of Watt. In 1773, the engine was removed to Mr. Boulton's works at Soho, and was fitted with a new cast-iron cylinder, the casting and boring of which were deemed no small achievement in those primitive days of mechanical engineering.

This first engine of Watt was, like that of Newcomen, only applicable to pumping, but Watt quickly saw by what modifications it could be rendered available for rotative motion. By a succession of brilliant inventions, comprising, amongst others, his parallel motion and his ball governor, he advanced to the final conception of the double-acting rotative engine, which became applicable to every purpose requiring motive power, and continues to this day, in nearly its original form, to be the chief moving agent employed by man.

To do full justice to the genius of Watt, we must consider the disadvantages under which he labored. In the present day, every contrivance is practicable in a constructive point of view, and the vast variety of devices used in modern mechanism, and applicable to new mechanical combinations, are made known to inventors in minute detail by the press. But Watt had no such facilities. He had to draw from his own mind what we can now choose from pre-accomplished invention, and his choice of means was restricted to the narrow limits of what was practicable in the rude workshops of the period. If we give due weight to these considerations, we shall be able to appreciate the remarkable originality of his mind, and the sagacity displayed in his invention. Watt lived to see his steam-engine bear fruit in marvelous utility to the human race; but he could have had no idea of the results it was destined to realize before the first century of its existence. It is impossible to contemplate these results without feelings of enthusiasm. To appreciate how much we owe to the steam-engine, we need only consider for a moment what our positions would be if we were deprived of its agency. The factories which clothe all the nations of the earth would be almost extinguished. The deep mines which supply nearly all our mineral wealth would be abandoned. The manufacture of iron would shrink into comparative insignificance. Horses and sailing ships would again become our only means of transit. All great engineering works would cease, and mankind would relapse into that condition of slow and torpid progress which preceded the subjugation of steam by Watt.

PERMANENT WAY.

Compiled and adapted from "Polyt. Centralblatt."

A great number of engineers are of the opinion that to obtain a solid and permanent railway, causing the least possible maintaining expenses, the wooden cross-ties should be removed, and replaced by more durable materials. The plans which have been designed for this purpose, are principally the following:

1. To lay the rails on stone blocks.
2. To lay the rails on piers of cast iron.
3. To replace the wooden cross-ties by iron ones.
4. To lay stiff and strong, or broad footed rails, directly on the ballast.
5. To lay the rails on longitudinal wrought iron sleepers, in the ballast.

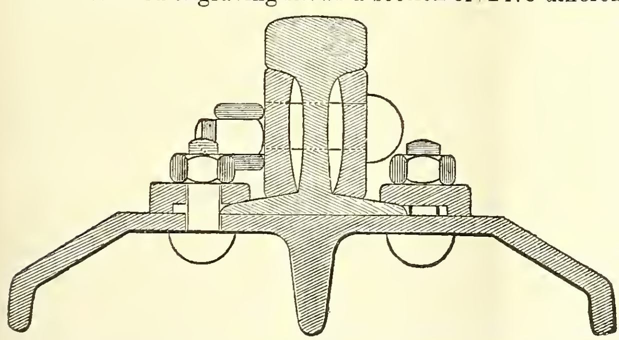
The first method has been introduced on some lines in Bavaria and Wurtemberg, and works satisfactorily when well and solidly constructed. The second method is in use on a larger scale in Egypt, Algeria, England and the East Indies, and a trial is just being made with it on the small route between Leipzig and Magdeburg. Both these systems of construction are not to be recommended for use on a new embankment, because when the latter settles they yield too easily, and cause disturbances in the track.

Iron cross-ties are used on some lines in France, Belgium and Spain. Vautherin's system, especially, has been introduced on the French Northern Railroad, and recently on the Saarbruck Railroad. The rails are fixed to the ties by wedges. This system is more appropriate to new railroads than the two former, as the width of the track cannot be altered by the settling of the embankment. But the construction requires much iron, and is, therefore, very expensive. It is, besides, to be feared that the wedges used may not stand long, and that they may widen the wedge holes, and become loose after some time.

The fourth method of constructing permanent way, consists in laying very rigid and strong rails directly on sand or gravel, or crushed stone. This method has been tried with satisfactory results on the Cologne Minden Railroad, where rails 8 in. high, made after the design of Mr. Hartwich, were used for the purpose. These rails were joined by fish-plates 2 ft. in length, with eight screws of 1 in. diameter. The plates are strong and well designed; their moment of inertia being equal to that of the rails. The cost of the iron on this road amounted to 2.65 Prussian thalers per foot ($1.85 gold). If the rail is laid directly on gravel, its foot has to be very broad to get a sufficiently large bearing, or the rail has to be very high to reach as deep below the surface of the gravel as possible. Both ways involve great inconveniences. A very high rail especially, is liable to tip over. Mr. L. Clasen, of Hanover, therefore proposed to lay such rails on a foundation of concrete, imbedded in the gravel. Concrete when well prepared, is a cheap, strong and durable material for railway substructure, and can be easily obtained everywhere. For the purpose of attaching the rail, Mr. Clasen proposes to lay a plate with a small rectangular hole into the concrete about 1 ft. deep, to leave a narrow hole open, extending from the hole in the plate to the surface of the concrete. A bolt, with a hook of peculiar construction at its lower end, would be inserted into the hole and hooked on to the rectangular hole in the plate. The rail would be kept in place by being screwed on to several of these bolts. The latter could be easily removed when broken, and replaced by new ones. The rails have to be joined by strong fish plates, with four screw bolts. To prevent the rails from giving way sidewise, it is proposed to join two opposite rails by wrought iron flats, laid below the foot of the rails, and bent upwards on both sides of the track. This plan has not yet, however, been tried practically.

A very successful trial has been made on the Nassau Railroad (Prussia), with the fifth of the above mentioned methods of railway construction.

The annexed engraving shows a section of



the arrangement. Wrought iron sleepers are laid in gravel or sand, parallel to the track. On these sleepers light rails are fixed by means of small plates, and short screw bolts, and joined by fish-plates. The width of the track is preserved by thin wrought iron cross-ties connecting two opposite rails.

As this system seems to be a decided success, we give in the following a more detailed description of it, as published in "Polyt. Centralblatt," by Mr. M. Hilf, of Wiesbaden.

1. *Rails.*—The rail used has a broad foot and pretty sharp angles below the head, so as to allow of the application of a strong fish-joint. Its weight is little over 51 lbs. per yard, which is about two-thirds only of the weight of the rails used on the same railroad with the ordinary wooden substructure.

The fish-plate has been recognized as the most reliable means for joining the rails. They are, besides, joined below, the ends of two adjacent rails being attached to the same sleeper. This gives a high degree of solidity to the whole system.

The rails have a length of 19 ft. $8\frac{1}{4}$ in., and are slotted in two places near the middle, and clinched by two of the fastening bolts to prevent the rails from creeping. Every rail is attached to the sleepers by eighteen screw bolts, the nuts of which work on small plates, which clasp the foot of the rail, as our engraving shows. The total weight of the eighteen bolts, nuts and plates, necessary to fasten one rail, amounts to 23 lbs. The fastening effected by these means is so solid that its safety is not much endangered if some of the nuts should become loose, which however happens but very rarely. The same straight sleepers are used for laying curved tracks. The bolt holes have then to be drilled into the sleepers so as to correspond to the required curves. Five different templets are sufficient to mark the bolt holes for all the curves of from 900 to 6,000 ft. radius. The sleepers have then of course to be laid in a position parallel to the tangent of the curve. The rail being light, does not want to be bent previous to laying, and a curved rail can be turned round when one side of its head is injured.

2. *Sleepers.*—The sleepers are easily rolled into the shape indicated by our drawing. They are all made of the same length, which is 19 ft. $2\frac{3}{4}$ in. They are about $\frac{1}{2}$ in. thick, and weigh $79\frac{1}{4}$ lbs. per yard. Sleeper and rail together are so strong that when laid on supports 3 ft. apart, they are not strained

beyond the limit of elasticity by a weight of 36,000 lbs. As the load pressing on the whole system when in use, is distributed on a pretty large surface, this strength offers more than sufficient security. The shape of the sleeper is such as to present two concavities below, into which the material that forms the bed can be rammed in solid. This material cannot, therefore, give way sidewise, but it becomes the more solid the greater the load pressing on the rail. In fact, the whole construction acquires the more steadiness the longer it is in use. The sleepers themselves are so strong that they will not have to be renewed for a very great number of years.

3. *Cross-Ties.*—There are three wrought iron cross-ties on every 20 ft. of track ; that is, on the length of one rail. They connect two opposite rails directly, having a screw at each end which passes through a corresponding hole in the web of the rail. Two nuts outside, and one inside of the rail, fasten the latter to the tie. The length of the ties is $5\frac{1}{2}$ ft. Three ties with their nuts and washers, weigh together 53 lbs.

The strength and number of these cross-ties is more than sufficient even in sharp curves. The double nuts on the outside are not absolutely necessary, but are safer, especially with sharp curves.

The cross-ties are easily detached, when rails have to be exchanged. The enlargement of the track in the curves can be exactly regulated by the ties and the nuts.

The total weight of the construction above described, is for the length of one rail as follows :

Two rails 19 ft. $8\frac{1}{4}$ in. long, 51 lbs. per yard	669 lbs.
Two sleepers 19 ft. $2\frac{3}{4}$ in. long, $79\frac{1}{4}$ lbs. per yard	1,016 lbs.
Thirty-six screw bolts, with nuts and small plates	46 lbs.
Three cross-ties, with twelve washers and eighteen nuts	53 lbs.
Two pairs of fish-plates, with eight screw bolts	44 lbs.
Total weight for one rail-length	1,828 lbs.
or 278 lbs. per yard.	

The total and full cost of the whole iron superstructure, including the laying, was $9\frac{26}{30}$ Prussian thalers per meter, or $6.32 gold, per yard of track. The expenses for maintaining a track of the above construction are very small.

A length of 490 yards of this track was laid in 1867, in the station at Asmannhausen, on the Nassau Railroad. The ordinary kind of rails was used. A part of the rails were fastened to the sleepers by rivets instead of screw bolts. 380 yards of the said track were laid in curves of 500 to 700 yards radius. Eight trains were run over the track daily. None of the rivets or screw bolts had become loose, and no part whatever of the track had been deranged at the end of the year 1868. The gravel on both sides of the rails and sleepers has grown hard on the surface, and the crust thus formed never shows the least cracks, which proves the solidity of the construction. The trains run smoothly over the track without any concussion at the joints of the rails. No bad influence of the weather has been observed, although the drainage of the track is very imperfect. The position of the sleepers has not been disturbed by a temperature as low as 5° F. above zero.

In consequence of the excellent results of this trial, a similar track was laid between Ober-Lahnstein and Ems, on the Nassau Railroad, a distance of about two German miles, containing several curves of 330 yards radius. This line is completed, and proves to be a perfect success. The trains run steadier and with less noise over this track than over the rails laid on wooden cross-ties. The iron sleepers lie perfectly firm. The rails do not alter their position in the least, not even when the cross-ties are removed, and when the trains run over the track at full speed. This shows that two cross-ties per rail would be quite sufficient, especially on straight lines. A part of the above mentioned line was laid down in such a manner that every single rail rested on a single sleeper, the joints being thus suspended. This was done because it was feared that the motion of the cars would not be perfectly smooth with fixed joints. This apprehension was, however, not verified, and as the latter arrangement gives the track a greater solidity, it will be preferred in future constructions upon this system. S.

The Creeping of Rails on a double track, where all the trains run way over them, has got to be a very serious matter with our old fashioned methods of laying. The spikes used with a common chair are utterly inadequate ; with a continuous-lipped chair they answer tolerably. But the Reeves chair makes a better joint than either—better than the fish-joint with low rails—and it entirely prevents creeping.

LIGHTING COAL MINES.—The awful loss of life which has been occasioned, both in this country and abroad, during the past few years by colliery explosions, is at last, we are glad to see, in a fair way to receive the attention it merits; and we trust that the next session of Parliament will not be allowed to pass without some material improvement being made in our legislation on the subject of colliery management. It is quite time, not only that the thoroughly efficient ventilation of coal mines should be rendered compulsory by law, but also that means should be adopted to ensure that the law is carried out. Quite apart from the ventilation, also, means should be taken to ensure the proper lighting of coal mines, and this lighting should be so effected that, even in the event of the ventilation of a portion of a mine becoming temporarily deranged from accidental causes, no harm could result. The safety-lamps now used, though no doubt excellent in their way, give but a very miserable light, and those who have studied the causes of past explosions, well know that these have been in many instances caused by miners opening their lamps to get a little extra illumination. The surfaces of a coal mine, in fact, possess such great light-absorbing power, that none but a very powerful light can be regarded as a really efficient one.

Bearing these facts in mind, Mr. Henry Bessemer, in a letter addressed by him to the "Times" a few days ago, has suggested a method of lighting coal mines which appears to us well worthy of careful attention. As some of our readers may be aware, Mr. Bessemer has been lately engaged in investigating the action of combustion under high pressures, and the results which he has obtained have led him to consider that lamps in which the combustion goes on under pressure exceeding that of the atmosphere, might be advantageously employed for lighting mines. Thus, he states, for instance, that an iron box, having one side fitted with a bull's-eye, or formed of thick plate glass, may be fitted with an ordinary gas-burner, supplied with gas from a gasholder above ground, and that the air to support combustion may be supplied to this box by a suitable pipe at a pressure of, say, 1 lb. per sq. in. above the pressure of the air in the mine, a small hole being left at the top of the lamp for the escape of the products of combustion. Under such circumstances not only would the light produced by the combustion of the gas be intensified, but the pressure within the lamp being in excess of the surrounding atmosphere, the latter would be prevented from entering, and consequently, even if an explosive mixture existed in the mine, it would be perfectly safe from ignition.

Such is Mr. Bessemer's plan, and an admirably simple plan it is. By the aid of a series of brilliant lights, such as he proposes, the galleries of mines may, as he says, "be lighted like a workshop," and there is really, as far as we can see, no good reason why this should not be done. The supply of air and gas, under suitable pressure, presents no practical difficulty, and by the aid of suitable reflectors, one powerful lamp, such as we have described, would be enabled to give a good light for some considerable distance around it. By the aid of easily contrived arrangements, also, some of the lamps might be made to a certain extent portable if required, but in such a case care would of course have to be taken to protect the glasses from accidental fracture. Mr. Bessemer states that he is "convinced that the thorough lighting of a coal-pit, and its ventilation so as to insure health and safety to the miners, are purely a question of £ s. d.," and in this opinion we perfectly agree with him. We do not consider, however, that in matters of this kind any question of expense should be allowed to interfere with the adoption of thoroughly efficient arrangements, and we think that it should be placed beyond the power of any colliery proprietors, actuated by parsimonious motives, to risk the lives of the men employed by them. As in the case of boiler explosions, the experience of past years has taught us that a knowledge of the risks to which they are exposing not only themselves, but others, is not of itself sufficient to make all men adopt means to avoid these risks; and it is, we think, time that both boiler owners and colliery proprietors should be made to feel their responsibilities more strongly. How this can best be done is a matter which we shall not discuss here, as it is to a certain extent foreign to the object of the present article, which was specially to bring before our readers the system of lighting we have already described, a system, we may add, which has not been patented. The fact of a good invention being public property, has but in too many instances proved to be a bar to its adoption, as it has been nobody's interest to show that it was the "right thing in the right place;" we hope, however, that Mr. Bessemer's plan may prove an exception to this rule, and that it may shortly be tested on such a scale as to demonstrate its practical merits.—*Engineering*.

STEAM ON CANALS.

Abstract of a paper read before the Institution of Mechanical Engineers at Newcastle, by Mr. Max Eyth, of Leeds.

In the application of steam power to river and canal navigation, the writer remarked, the greatest obstacle to be encountered had been the loss of power that was inseparable from the ordinary methods of propulsion by paddle-wheels or screw propellers. As the resisting water formed the fulcrum upon which the bearing was taken for propelling the vessel, the result was that a great quantity of water was put in motion, and a considerable amount of power exercised without any useful effect being produced. Thus even under the most favorable circumstances, when working on a broad sheet of deep water, the ordinary propellers lost from 40 to 50 per cent of the power applied to them; and, under the peculiar circumstances met with on rivers and canals, their useful effect was frequently reduced to less than 25 per cent of the power applied. On canals, the increased difficulty to be encountered arose from the presence of locks, the small section of water through which the boats had to be driven, and the swell produced by the increased speed of the boats, for which the small section of water was not originally calculated. Moreover, as the only admissible means of propulsion was by screws or paddle-wheels placed at the stern, the water put in motion by them was withdrawn from the stern of the tug, and thrown against the bows of the boats in tow; the water-level in the canal was thereby disturbed, and the hollow created at the stern of the tug had to be filled up by the water in front of the tug running backwards through the narrow passage left between the tug and the sides of the canal. The consequence of this was that engines of considerable power had to be used for towing a given freight; and hence, owing to the small size of the locks through which they had to pass, it was of the utmost importance that the engines employed should occupy as little space as possible in the holds of the vessels, in order that the cost of steam propulsion might not be further increased by a source of diminution in the amount of freight that could be carried. As it was admitted that a dead pull from a fixed point was undoubtedly the most effective mode of gaining power, it had now been determined to adopt a system on canals and rivers of towing by means of a fixed wire rope and clip drum. The rope was laid in the bed of the river or canal from end to end, being anchored only at its two extremities, and an engine on the deck of the boat was then attached to the rope, and wound itself along to its destination. The idea was not altogether new, as attempts had been made on the Rhine by the French Marshal de Saxe, as early as the year 1732, to transport war material through different rivers of the country by means of a horse windlass on the boats, which wound up a rope made fast on the bank of the river at the extreme end. In 1820, a regular service on the same principle was established on the Rhone, by Tourasse, and it successfully overcame the difficult portions of the river between Givers and Lyons. After noticing the drawbacks of the plan, however, and the many obstacles in the way of a free use of chains or winding drums, the paper added that the present system—consisting of a clip drum working along a submerged wire rope—had been invented and matured by Baron Oscar de Mesnil, a Belgian gentleman, and the author himself; the first experiment having been made at Leeds, in 1866, for Joseph Fowler & Co., and since repeated more extensively on several American canals and also in Belgium. The first application of the submerged wire was made on the river Meuse, where a line 42 miles in length—from Namur to Liège—had been in successful operation since 1868, and was now being extended 90 miles through the Canal de la Campine to Antwerp. Having described the Canal de la Charleroi, in Belgium, the writer added that one of the boats on it was 42 ft. long, by 8 ft. broad, and drew 3 ft. water; while the wire rope, $\frac{5}{8}$ in. in diameter, wound round a 5 ft. clip drum. In addition to these there was a winding drum used for the purpose of obtaining a sufficient amount of slack in the rope for enabling the tug, when off the rope, to hitch on again at any place without delay. The speed of the engines here, 10-horse, was 80 revolutions per minute with 90 lbs. pressure of steam, and the speed varied from one to three miles; but on the river Meuse they had engines of 14 horse-power, working up stream at from three to six miles an hour, although on the downward journeys this could be increased to ten miles by running the engine at 120 to 130 revolutions. In some places, also, they had smaller boats fitted with portable engines—engines that could easily be transferred from one boat to another; and while these were, by a very ingenious contrivance, enabled to pass through the narrowest parts of a canal or the lowest bridges, they could easily travel at $2\frac{1}{2}$ miles an hour with two 200-ton barges fastened behind them. The ropes were in all cases laid along the side of the deck, and never being very long exposed to the air they were not liable to injury by oxidation, neither were they subject to fracture or obstruction on the bed of the river. The rope used on the river Meuse was only 1 in. in diameter, of iron wire, the greater part being galvanized, and having a breaking strain of 14 tons. The weight was $4\frac{3}{4}$ lbs. per yard, and cost, including the laying down, £93. The maximum work done by one tug of 14 horse-power, was towing 18 boats containing a total cargo of 1,000 tons; while, by another, 1,500 tons of freight was towed by 10 boats. Both trips were made up stream, and at from $2\frac{1}{2}$ to 3 miles an hour, including stoppages. The average work of the tugs was to tow 700 to 900 tons of cargo, in 8 or 12 boats of different sizes —the steering in all cases being good— while the average amount of coal consumed by the 14-horse tug amounted to three-quarters of a hundredweight per mile, and the working expenses to £22 per month. The cost of towing on the canals, where the system was now in operation, amounted to not more than .05d. (or one-twentieth of a penny) per ton per mile, including the working expenses, the management, the interest, and the redemption of capital. This result was not only another illustration of the great advantage which inland navigation possessed over any other mode of carrying heavy traffic where speed was not required, but it also proved the important commercial value of this particular mode of towing, as compared with any of the other methods hitherto in general use. The average cost of towage by animal power on four English canals, amounted to .35d. per ton per mile, and on seven French canals was .27d. With paddle tugs on the Thames the cost was .48d., and on six rivers in France it was as high as .80d. per mile. The employment of screw tugs on three English canals resulted in an average cost of .27d.; whilst towing by boats carrying their own machinery cost, on seven English canals, .20d. per mile. In conclusion, the author remarked that while railways had undergone so wonderful a development during the past thirty years, the quieter, but often more important, mode of transporting heavy goods by inland navigation had remained comparatively neglected. It was true that the natural features of England were not very favorable for inland navigation, although there was in the United Kingdom a total length of 2,000 miles of navigable water courses; but on the Continent, in the colonies, and especially in India, there was a vast amount of traffic for which no better highways could be found than those already traced by nature in the rivers and streams penetrating the interior of the country. The system of wire rope towing that had now been described, placed inland navigation in a similar relative position to that in which the road traffic was placed by the introduction of the railway and the locomotive. By means of the clip drum, the tug obtained a hold upon the flexible rope laid on the water course precisely in the same manner as the driving-wheel of the locomotive took hold of the rigid rail upon which it ran; and the great advantage of steam-power might, therefore, be similarly brought to bear on the movements of vessels in water—leaving to railways all their superiority in regard to speed, but restoring to rivers and canals their advantages in reduction of traction.

MECHANICAL FIRING OF STEAM BOILERS.

By Mr. John Daglish.

Abstract of a paper read before the Institution of Mechanical Engineers at Newcastle.

The first part of this paper contains the results of a series of experiments that were arranged and carried out by the writer at Rainton Colliery, chiefly for the practical determination of the question of the utility and economy of side water boxes in connexion with Juckes' furnaces, and incidentally to ascertain the advantage derived from covering boilers, and the best materials for that purpose. A second series of experiments were then given that were conducted at Seaham Colliery, for the purpose of practically ascertaining with certainty the advantages obtained by the use of mechanical apparatus as compared with firing by hand, and the comparative advantage of various systems of mechanical apparatus. Incidentally, attention was drawn to other points, and experiments were made to ascertain the best rate of motion for the bars, thickness of fire, and distance of boiler from firegrate. A third series of experiments were then given that were conducted at Silksworth Colliery, for the purpose of determining the relative advantage of the Cornish boiler for colliery purposes, as compared with the plain cylindrical boiler, prior to erecting a large number for the extensive new coal winning which is now proceeding at Silksworth. Incidentally, the experiments were carried out with different qualities of coal, for the purpose of ascertaining their comparative economic effects. The first series of experiments were made at the pumping engine at Rainton Colliery, which is well adapted for experiments of this kind, as the engine is going continually at an uniform speed. The boilers are in one range, are all of the same size and description, and the temperature of the water was taken alike throughout. They are fitted with Juckes' mechanical firegrate, consisting of an endless chain of short longitudinal bars, traversing forwards with a slow, continuous motion, and thus conveying the fuel from the hopper by a self-acting operation. Nos. 1 and 2 were covered with one description of boiler-covering composition, and were fired by Juckes' mechanical furnaces, 4 ft. broad; while two wrought-iron pipes, 2 in. in diameter, were placed on the inner end, $1\frac{1}{2}$ in. above the bars. These pipes were necessarily exposed to the action of the furnace heat, and, in order to prevent them from being burnt, were constantly kept filled with water. Nos. 3, 4 and 5 boilers were also fired by Juckes' furnaces, to which were added Coulson's water-boxes. These are the full length of the furnaces, 7 in. square, made of half-inch wrought iron; on the inner end they are connected with the boiler by pipes, and have at the outer end a sludge pipe, to remove any scale from the boiler. Nos. 3 and 5 boilers are covered with different kinds of boiler-covering composition, whilst No. 4 is not covered at all. The height of the bottom of the boilers above the fire bars was 2 ft. in three of the boilers, and 1 ft. 6 in. in the others. The quality of coal used was peas, or screened small steam coals; the same quality being used in all the experiments, and the exact quantity of coal used was carefully noted. The time taken in consuming the coals was also noted, together with the number of gallons passed through the special feed pipe; all connexion with the other boilers being shut off. The strokes of the engine were also taken during each experiment by means of engine counters. The result of these experiments may be generally stated to be:

	Pounds of water evaporated per lb. of fuel.
1. With boiler covering, without water-boxes, and with boilers 2 ft. above firegrate	4.83
2. Without boiler covering, with water-boxes and boiler, at 1 ft. 6 in. above fire-grate	4.66
3. With boiler covering, with water-boxes, 1 ft. 6 in. above fire-grate,	5.02
4. With boiler covering, with water-boxes, 2 ft. above fire-grate	5.38

The advantages of water-boxes in increasing the evaporative power of a boiler, as well as in the increased economy of fuel, are therefore very considerable, but those advantages are to a great extent neutralized by the difficuties and increased expense in upholding those boxes. There might be circumstances, however, when their use would be attended by ultimate economy. The advantage of having the boilers at a distance of 2 ft. above the firegate, as compared with 1 ft. 6 in., is also shown by these experiments. With 1 ft. 6 in. distance the effect was 5.02, as compared with 5.38 with a distance of 2 ft., showing an advantage in the latter of more than 6 per cent. It is also found in practice that the boiler is much less injured by the action of the heat at the greater distance. The second series of experiments was made with the range of boilers of the Seaham winding engine, and they are under cover of a boiler house. The boilers are all of the same dimensions, being ordinary egg-ended cylindrical boilers, with a straight flash flue going into the main flue. No. 1 boiler was fired by hand; the heated air, after passing along below the boiler, returns by a side passage, and travels all around the boilers before entering into the chimney. After the wheel flue experiments were made, the flue of this kind was made into a straight flash flue. No. 2 boiler was first fired by hand, with a straight flash flue running direct into the main flue, and was afterwards fitted up with Stanley's self-feeding mechanical furnace. No. 3 boiler was fired with Vicar's self-feeding furnace. Nos. 4 and 5 boilers were fired with Juckes' furnace, of the same description as those already experimented on at the Rainton Colliery pumping engine. From the experiments shown in the accompanying table, the following deductions may be made: First, with hand firing, the quantity of water evaporated per pound of coal, with a flash flue, is 6.66 lbs. as compared with 5.22 lbs. with a wheel flue; and the total quantity of water evaporated is 441 gallons per hour, as compared with 433 gallons per hour, showing the marked advantage of the flash flue over the wheel flue, not only in the economic effect of fuel, but also of boiler space. It is probable, however, that this amount of economic effect (6.66) is considerably higher than that obtained under ordinary circumstances, as the fires were more regularly attended to than is usual with hand firing. Secondly, Juckes' furnaces. This apparatus, invented for firing steam boilers, has been in operation some time in this district, and has lately been adopted very largely at many collieries in the north of England. The advantages of this furnace are, perfect combustion of smoke, and great regularity in raising steam; the saving, in common with other mechanical appliances, in the wear and tear of boilers and in manual labor in stoking, the latter amounting probably to £200 per year per boiler. In comparison with hand firing, it does not seem to possess any great advantage in economy of fuel, the comparative economic effect being 5.09 as compared with 6.66 for hand firing; but the latter is probably a much higher result than what is usually attained in practice. Like all other mechanical appliances, it requires a certain amount of care and attention in its use; but on the whole it may be said to be successful and economic in application. It is not well adapted for using Duff coal, although this is done in some instances when the Duff is washed. Thirdly, Vicars' furnaces. Of all the mechanical apparatuses for firing steam boilers, none seem to be so successful as Vicars', as arranged at Seaham Colliery, though this apparatus, erected elsewhere, seems not to have worked satisfactorily, which was probably owing to the improvements recently made in the apparatus. These now consist of three distinct appliances. The traversing bars, intended to give progressive motion to the incandescent fuel, by a slow alternate and intermittent longitudinal motion; second, the pump feeders, which alternately press a regular supply of coal from the hopper to the bars; third, the water troughs, in which the fire bars are immersed, and which are absolutely essential, as no ordinary fire bars can withstand the intense heat of the fire. This furnace was in constant operation at Seaham Collieries for nine months without requiring any repairs, and in all respects it has been most successful and economic. When using the same class of coal (peas) as in the hand-firing experiments, the economic effect was 7.14, as compared with 6.66; but the maximum results of this furnace have probably not yet been obtained, nor the best conditions as to thickness of fire ascertained, the high amount of 8.78 lbs. of water evaporated per pound of coal being in one instance obtained. This furnace is very efficient in its action in avoiding the formation of smoke. The great advantage, however, attending the use of the furnace is its applicability to the use of Duff coal, or dust coal, with high economic effect. It will be observed that with dust coal the economic effect actually reached is 6.84 lbs. of water per pound of coal. Taking the consumption of fuel in one of these experimental boilers at six tons per day of 24 hours, and taking the comparative price of Peas and Duff coal at 3s. and 1s. per ton at the pit, the commercial economy effected by the use of these furnaces over any other mechanical apparatus not adapted to use Duff coal will be from £200 per year per boiler. The evaporative power of the apparatus does not appear by these experiments to be equal to that of Juckes' or hand firing, although this may arise, as before stated, from the fact of its maximum power not being yet perfectly developed. A somewhat interesting circumstance may be observed in these experiments. The fire-bars used in this special fire are 5 ft. 4 in. in length, whilst those in Juckes' apparatus are 6 ft. 6 in. in length; but although the heat of the fire in Vicars' grate was much more intense than in the Juckes', the pyrometric observations in the flue beyond the boiler invariably showed much lower temperature from the former than from the latter. It would seem, therefore, that the heat developed in the grates of the Vicars' is of considerably higher intensity than that of the Juckes', and as effectual in its action on the exposed surface of the boiler, so that the absolute heat remaining on arriving at the flue is then reduced below that of Juckes'. The experiments with Stanley's apparatus give very irregular results, showing that a lengthened series of experiments, as to speed of dispersers, thickness of fire, etc., would be required before the maximum effect could be regularly attained. In this apparatus, the coal falls through crushing rollers on to two dispersers, or rapidly revolving discs with radiating ribs, which scatter the coal uniformly through the fire by centrifugal action. The advantages of this furnace are that it permits of the use of Duff, or dust coal, and a comparatively large amount of fuel can be consumed per square foot of fire-grate surface. As compared with hand firing, a much lower economic effect is exhibited, being 4.74 against 6.66; but it is more than probable that this arises from the Stanley apparatus not being in all respects arranged to obtain its maximum effects. A few experiments were made with this furnace after the addition of Whittaker's traversing bars, but not sufficient to yield any reliable data. The third series of experiments with single tubular boilers were made with two boilers erected at Silksworth Colliery, for temporary purposes, which were fortunately of exactly the same size, and were constructed with a single tube. They had been previously in use at the Londonderry blast furnaces blowing engine, and were then set over the fire-grate, the draught returning through the tube and thence round each side of the boiler. At Silksworth one of these boilers is set in a similar way, the other having a fire-grate fitted up in the tube and used as a Cornish boiler. This series of experiments was intended also to show the useful effects of external heating surface, and by an arrangement of dampers the smoke could be either taken at once up the chimney, or made to pass all around the outside of the boilers by the external wheel flue. The following are the chief deductions to be drawn from these experiments: First, the advantage in No. 1 boiler, of using the wheel flue, overtaking the smoke direct through the tube to the chimney, is as 5.51 to 4.87; secondly, there is a slight disadvantage in No. 2 boiler using the return tube through the boiler and the side flues, instead of taking the flame direct from under the boiler to the chimney, being as 4.72 to 4.94. The general results of these experiments tend to show the advantage of flush flues, having the usual large heating surface. The most important point, however, to be deduced from the experiments was the small evaporative power of the boilers when fired through a single tube, as compared with the result of firing underneath the boilers, being only 604 and 690 gallons evaporated by the former as compared with 1344 and 1243 by the latter method, the economy of fuel being about the same in each case. The chimney, however, used for these boilers was only temporary, and not capable of producing a draught sufficient for the wheel flues. This fact renders it impossible to make any comparison between these experiments and those made at Seaham Colliery. It must be borne in mind that these boilers are by no means fair specimens of the Cornish boilers; and arrangements are being made to carry out a series of experiments to ascertain the evaporative power and economy of the Cornish boiler as compared with cylindrical boilers. These experiments will be made with boilers recently erected at Hetton Colliery, of improved construction. In conclusion, the writer expressed his thanks to Messrs. P. B. Hood, Wm. Armstrong, jr., and Emerson Bainbridge, for their careful attention in carrying out and tabulating the experiments.

ACCUMULATED HYDRAULIC POWER.

From "The Engineer."

We divided this subject into five heads in in our first article,* namely: (1) Cost of generating the power; (2) Loss by friction; (3) The cost of the machinery; (4) Convenience of application; and (5) Cost of maintenance. These heads we only treated generally and collectively in that article, as our object was to take a sort of "bird's-eye view" of the question; to be afterwards amplified in dealing with each point in detail. In dealing practically with complex problems it is impossible to adopt any system of division or classification which can be adhered to throughout. It is necessary at certain points to admit of a little overlapping of the divisions. We shall endeavor to keep the various divisions as distinct as may be, but we shall not hesitate to sacrifice mere classification to the more important considerations of clearness and practical convenience. Having thus far explained the "base of operations," we shall proceed to the discussion in detail of the "cost of generating the power."

Water pressure, such as we are discussing, can only be obtained by pumping into an accumulator, as the high pressure required exceeds that of any natural "head." As, for instance, in the case of the extensive sets of hydraulic cranes, hoists, &c., which have been introduced by Sir W. G. Arm-

* See Van N.'s Magazine, September, page 778.

strong & Co., the pressure most commonly adopted is 700 lbs. per square in.—a pressure corresponding to a head of about 1,600 ft. It is needless to observe that such a "head" as this is not obtainable either naturally or artificially in any of those localities where it would be commercially available. Even the lower pressures of 300 lbs., and 500 lbs., per square in., which have been adopted in our chief steel and iron works, would require respectivelyel evations of 700 ft. and 1,150 ft. These pressures, therefore, are only obtainable by the use of a loaded accumulator, and *à fortiori*, those higher pressures of two and three tons per in.—of which we shall treat in the course of our present inquiry—are necessarily so obtained.

We shall first consider those cases where a steam engine is employed to work the pumps, such being the rule, though it will be necessary to discuss some very important exceptions. With the question of the economic production of steam in the boiler we have not to deal, nor is it within our present purpose to discuss any points affecting the engine *per se;* though both these parts of the general apparatus must play a most important part in determining the question of absolute economy. Their selection lies, however, in the province of steam engineering.

It will be necessary, nevertheless, to consider the use of the steam in the engine as far as the same is affected by the construction of the hydraulic apparatus and the mode of conveying power from the engine to the pumps. The simplest way of looking at the work to be done is to consider the accumulation of the power merely in the light of a load raised a given height. The "head" of water which would correspond to the pressure per square in., is the measure of the height to which the load is to be raised, if such load be taken as the weight of the water pumped. If, on the other hand, the load on the accumulator be taken as the load to be raised, the distance through which the ram of the accumulator is raised is the measure of height. In the first case we have a small load raised to a great height; in the latter a larger load lifted through a less height. The first represents the amount of work by a theoretical expression, while the latter gives the actual state of the case. We shall have occasion to refer to each in its place, but we may call attention to the fact that the first is by far the more convenient, as the quantity of water pumped can be at once stated, or, in practice, ascertained by measurement; the total lift of the ram of the accumulator could, on the contrary, only be ascertained by complicated systems of addition and substraction, the actions of the machines keeping the ram in a constant state of upward and downward movement. We have got, then, a load, which is continuous, to be lifted to a given height. This load is, by its very nature, inelastic, and to raise it by an elastic force, as of steam, requires special adaptations to guard against waste of power. Clearly, the worst possible way to raise a load by steam power would be by the direct action of the steam, as, expansion being impossible, the steam must be discharged with the major portion of its energy undeveloped. Yet we have seen this done where an engine of the "direct-acting" class, with the steam piston-rod passed through the ends of the steam cylinder into two small hydraulic cylinders, was used for pumping into an accumulator at a pressure of about two tons per inch. Not only is there here the ruinous waste of steam, but as the speed of the steam piston cannot exceed that of the hydraulic pistons, a very large steam cylinder would be required to work a sufficient quantity of steam.

The speed of hydraulic pump plungers working at high pressures must be slow while a high speed of piston is advisable for steam engines, as reducing the cost and size of the engine and also facilitating expansion. The steam piston should run at from five to ten times the speed that the hydraulic plungers work at. It is therefore necessary that some sort of intermediate gearing should be used between the engines and the pumps; and also that provision should be made in the engine for a sufficient power of momentum to enable expansion to be fully carried out. There is a great advantage in the facility with which expansion can be carried out in engines employed in pumping into accumulators. No self-acting expansion gear worked from the governor is necessary; the load being constant, the cut-off may also be constant. Where engines are specially made for this work, it is advisable to use two cylinders connected to cranks set at right angles on one shaft. On this shaft should be a fly-wheel of a weight suited to the rate of the engine and the degree of its expansion. A second shaft should, by means of short, strong cranks, drive the hydraulic plungers, these cranks being opposite to each other. This second shaft is to be geared to the first by accurately made tooth gearings of the proportions before mentioned. Such a construction as this is simple and in every way effective.*

It is requisite to provide an arrangement to the accumulator, such that when the ram reaches a certain height, the supply of steam to the pumping engine may be cut off; and also that when the ram falls a little below that point, the engine shall be retarded. The valves of the pumps and accumulators must be as straight in the passages as they can be made, and the pipes between them as free from bends—particularly sudden ones—as may be. The propelling of the water through bends and all confined passages is analogous to the drawing of a loaded carriage over stones or other impediments, and seriously increases the load against the engine. It is also a mistake to use pipes of small diameter, since there is a loss of power, not only in increasing the velocity of the current of water, but also in the greater surface presented by such pipes in proportion to their area. In employing long ranges of pipes it is better to put an accumulator at each end. The pumps should in all cases charge the accumulator by pipes distinct from the service pipes, which convey the water to the machines, as otherwise there will be continually opposing currents in the pipes when the machines are in use.

In some situations it may be found advantageous to work the pumps by means of a water-wheel or a turbine. The principles laid down in treating of the use of a steam engine for this purpose are applicable to such cases, except as regards the remarks about securing expansion. With the water-wheel or turbine the motor and the load are alike inelastic. From the shaft of a water-wheel the hydraulic pump plungers would be worked direct, while from a turbine a very great reduction of speed would be required; but in neither case would the addition of any "vehicle of momentum" be requisite.

We have spoken entirely of loaded, to the total exclusion of atmospheric accumulators, for the following reasons: In charging an atmospheric accumulator the diagram would show a curve of compression indicative of the power required for the work of charging. In using the pressure it would be impossible to obtain anything even approaching the reverse curve; therefore a serious waste of power must result. But this is not all. A very considerable amount of heat must be evolved which is totally lost; while there is yet further the weighty practical objection that the pressure continually diminishes as the machine operated moves. The inconvenience and loss thus caused are very serious, as a very great amount of power is used, and there is the least of it where the most is required. These shortcomings are in themselves sufficient to condemn the atmospheric accumulator; added to these is the very great risk of keeping air at so great a pressure. In most cases where atmospheric accumulators have been put up they have since been abandoned. The inducement to use them lay in their small first cost, and the absence of working parts to keep in repair.

There is one advantage appertaining to the atmospheric accumulator, namely, its causing little or no shock to the machines and fittings. With loaded accumulators as usually made, this shock is very injurious, and is only partially met by "relief" valves; in fact, the "relief" valve is usually fitted to ease the shock in stopping the machines by letting back the pressure against the accumulator. The load on the ram ought to be suspended on strong but lively springs, to take up the momentum of the load after a "fall." We have ourselves seen a load of twelve tons dropped 9 ft. with such quickness as to be practically equal to a free fall of that distance. For such a load to be suddenly stopped by an inelastic fluid like water must be eminently injurious to all the fittings and joints. Such injuries might be to a great extent guarded against by the adoption of efficient springs. In the annular "dished spring"—a simple steel washer—invented by Mr. F. A. Paget, C. E., and extensively applied to similar purposes on railways in France, we have just the thing required—a spring which can be placed round the rod by which the load is suspended, thus occupying little room, and capable of any amount of reduplication. The cheapness of these springs—which will do in Bessemer steel—is of importance as regards the question of cost which we are discussing.

Where machines are at long distances from the accumulator, it may be advisable in some cases to put "relief" plungers in small cylinders, with either weights or springs to absorb some part of any sudden shock occurring. In all cases where the

---

* Before saying too much about the simplicity of this engine, the author should look into the Worthington duplex pressure pump used in American steel works.—*Ed.*

work is heavy and intermittent, particularly if the power has to be conveyed long distances, its generation and conveyance by hydraulic apparatus will be a source of economy.

The economy of having a constant load against the engine has been already pointed out; and the economy of conveyance through long distances will be perceived from the fact that water pressure conveyed through upwards of two miles of pipes showed no perceptible loss of power. Shafting, on the other hand, if carried to any considerable length, absorbs a great deal of power to overcome its friction, entails a constant expense for lubrication, and is subject to considerable wear and tear. In conveying power by water, the distance makes but little difference in friction, there is no expense for lubrication, nor is there much wear and tear. Beyond this, pipes are cheaper to lay than shafting, can be laid where shafting cannot, and do not require protection from dust.

As against these sources of economy may be set the fact that, when not fully loaded, there is a proportionate loss of power with hydraulic machines, since the power used is always the maximum, whatever the load may be. It is questionable, however, whether the economic working of the prime mover does not more than counterbalance this; and while with shafting, machines must be started and stopped suddenly, with hydraulic pressure any graduation can be obtained. There is also a beautiful steadiness of motion—due to the want of elasticity in the water—which is of great value in most mechanical operations. We shall have a better opportunity of speaking of this latter advantage in dealing with the fourth division of our subject.

In connection with the cost of generating and accumulating the power, we would call attention to the feasibility, in many cases, of aiding the pumps by returning the water under pressure from a descending load. Take the case of a lift, where heavy wagons or cages have to be raised full and sent down empty. It would, in such a case, be possible to effect a considerable economy by leading the exhaust pipe direct to the pumps; as whatever might be the pressure exerted by the descending load, to that extent would the engine be relieved, and a corresponding economy effected. A case of this kind occurred at the Mersey Ironworks. A steam pressure of 45 lbs. was required to charge the accumulator when the water was discharged from the exhaust in the ordinary way. On changing the arrangement, so as to carry the exhaust water in confinement to the pumps, 25 lbs. sufficed. The merit of this arrangement is due to Mr. W. Clay. A somewhat similar arrangement has been for some years in use at Newport in Monmouthshire. In this case a small ram is driven back against the pressure of an accumulator by the descent of a box loaded with coal; such box being then discharged into the colliers' hold, is raised by the power accumulated by its descent, the difference of the weight when empty allowing for the friction of the apparatus. In some instances it is preferable to use a counterbalancing weight. These contrivances are, however, noticed here merely as means of attaining economy in the power. Their further discussion will come under the head of designing hydraulic apparatus.

We have advanced sufficient proof of the comparative economy of accumulated power for many purposes; its absolute cost will of course greatly depend on purely local causes, such as cost of fuel and labor.

FEED WATER.

ITS CHEMICAL AND PHYSICO-CHEMICAL EFFECTS.

F. A. Paget, Esq., C. E.

From "The Locomotive."

The wear and tear of a boiler which occurs in the form of corrosion, properly so-called, may be divided into two principal kinds: (1) internal and (2) external. The progress of both is necessarily intensified by the mere effects of temperature; each, however, has its strongly marked, distinct character—not merely as to position, but also as to origin and results.

A steam boiler is in the position of a vessel into which large volumes of water are continually forced; while the heat applied, driving off all volatilizable matter, leaves behind a concentrated solution with a chemical character dependent on that of unvolatilizable matters in the feed-water. The specific gravity of the substances found in the water naturally causes them to sink towards the bottom, at which part the solution is generally more concentrated, however much it may be stirred up by the ebullition. Mr. J. R. Napier lately stated that a piece of zinc "about 4 ft. long, by 3 in. broad, by $\frac{3}{16}$in. thick, placed in a marine boiler for three weeks" to a depth of 18 in. in the water, showed a corrosion which rapidly decreased "up to the highest part, which, in the steam, appeared to be little affected."* This accounts for the fact that all boilers, even those internally fired, like locomotive boilers, have their plates most affected towards the bottom, and that internal corrosion always shows itself to a greater extent below the water line. The *bouilleur* of the form of boiler known as the French boiler, is also generally more affected than any other part. To resist this sort of slow action, it is clear that the more the bulk of metal the better, and it is for this reason that the bottom plates of most marine boilers are made thicker, while these same plates in locomotive boilers have to be often renewed. Any chemical or physico-chemical action of the kind is of course intensified by temperature, and this is one of the causes why externally fired boilers give way most, a little in front of the furnace. But the plates above the water line also get more or less corroded, and not merely with the usual character of rusting, but in that peculiar form known as pitting, which generally shows itself much more strongly marked below the water-line.

The presence of a concentrated solution of an acid or alkaline character, kept at a high temperature for years in contact with iron plates, would be sufficient to account for much corrosion. But the internal corrosion of steam boilers has many features of such a mysterious character, that no accredited explanation of its attendant phenomena has yet been put forward. In the first place, plates thus attacked show a number of irregular holes like a pock-marked human face, or like the small craters seen on the moon's surface.

The writer has also sometimes observed two or three little irregular excavations like this in a plate otherwise showing a large surface quite intact. Sometimes the plate is most pitted round a projecting bolt; at others, one plate will be perfectly sound, while that riveted to it will be almost eaten away, both having been the same time at work, and under, of course, apparently exactly similar conditions. With locomotive boilers this pitting has been ascribed to galvanic action between the brass tubes and the iron plates. But it is notoriously well known to locomotive superintendents, that boilers with iron tubes are often worse pitted than those which have run the same distance with brass tubes. Besides, all iron boilers, with or without brass, whether used for stationary, locomotive, or marine purposes, are subject to pitting.

An explanation which seems to meet all the circumstances of the case is the following: Mr. Mallet, in a report addressed to the British Association, some years ago, showed that wrought-iron and steel (blister-steel, probably) "consist of two or more different chemical compounds, coherent and interlaced, of which one is electro-negative to the other." In fact, ordinary wrought-iron, being also welded up from differently worked scrap, is far from being an electro-homogeneous body. In a boiler, the hot water, more or less saturated with chemical compounds, is the exciting liquid, and the electro-positive portions of the plates are thus quickly removed to a greater or less depth. This explanation meets most of the known circumstances with respect to pitting; it even, in a great measure, explains how plates above the level of the water, especially in marine boilers, get very rapidly corroded in portions, while another part of perhaps the same plate is scarcely affected. The concentrated water in a marine boiler is known to be generally acid. "Of all the salts contained in sea-water," says Farraday,* "the chloride of magnesium is that which acts most powerfully" on the plates. He shows that a cubic foot of sea-water contains 3.28 oz. of this salt; and, at the same time points to the danger of voltaic action in a boiler through the contact of copper and iron. In a smaller degree the contact of cast with wrought-iron, or between the different makes of wrought-iron in the same plate, or between contiguous plates, acts in the same way. It is not improbable that some hydro-chlorate acid is present in the steam of marine boilers. "Mr. J. C. Forster† has tested some of the condensed steam from the safety-valve casing, and from the cylinder-jacket of the Lancefield, and found both decidedly acid.‡ With an exciting liquid in the condensed steam, it is thus explicable how the plates of marine boilers often get corroded in a most capricious manner; while at the same time, the current of

* Institution of Engineers in Scotland, Session 1864–5.

* Fifth Report of the Committee of the House of Commons concerning the Holyhead Roads, p. 194.

† Institution of Engineers in Scotland, 1864–5. Introductory address, by Mr. J. R. Napier.

‡ When a solution of chloride of magnesium is evaporated nearly to dryness, the salt and the water are decomposed, magnesia and free hydro-chloric acid being formed; or $MgCl + HO = MgO + HCl$.

steam would create a certain amount of friction on the oxide, clearing it away to act on a fresh surface.

The crucial test of this explanation of pitting would be the observation of the absence of the phenomenon from plates of an electro-homogeneous character. This homogeneity could only be expected from fused metal, such as cast steel. Accordingly, while the writer was in Vienna a short time ago, he was assured by Mr. Haswell, the manager of the Staatsbahn Locomotive Works, that some locomotives made of cast steel plates, in 1859, for the Austrian Staatsbahn, had been working ever since without showing signs of pitting, though under similar conditions iron plates had severely suffered in this way. Pitting may thus be fairly defined as a form of corrosion localized to particular spots by voltaic action. It is also probably aggravated through the motion of the plate by mechanical action, and the expansions and contractions through alternations of temperature. All boilers are most pitted near the inlet for the feed-water, and with inside cylinder locomotive boilers there is generally more pitting at the smoke-box end—no doubt caused by the more or less racking action on these plates. A state of corrosion at particular spots would probably be kept up to a greater intensity by the incrustation being mechanically thrown off. With a quicker voltaic action, caused by any unusual intensity of the exciting liquid, the sides of the cavities in the plates would be sharper and less rounded off; as in the case of a boiler fed with mineral water from ironstone workings, which exploded last year at Aberaman, South Wales.

The fact that pitting occurs in marine boilers when distilled water from surface condensers is used, does not effect this explanation. Water distilled in this way, from whatever cause, after repeated boiling, is stated to carry the salinometer even higher than sea water, thus proving that it is not pure.* In the next place there is the absence of incrustation, which to some extent protects the plates of boilers from the chemical action of its contents. In this way the mechanical buckling of the plates—directly and indirectly causing the furrows we have spoken of—by continually clearing particular lines of surface from incrustation and oxide, reduces these particular spots, with respect to corrosion, to the condition of the plates of a boiler fed with water which deposits no incrustations. Corrosion will also act more rapidly at a furrow through mere increase and renewal of surface. To resist that form of internal corrosion specially known under the name of pitting, a maximum of electro-homogeneity is evidently required in all the component parts of the boiler.

While the action of internal corrosion, often very equally corrugating the plates over a large surface, as a rule scarcely, at any rate only gradually, affects their mechanical strength, external corrosion, being localized to particular spots, is of a much more dangerous character. The one is gradual and easily perceptible, while the other is rapid and insidious in its progress. Apart from accidental circumstances affecting the brickwork on which a stationary boiler is erected, or the outside of the bottoms of marine boilers, it is clear that external corrosion can only occur through leakage. When leakage takes place through a crack in the plate caused by mechanical action, or at a hole burnt out by heat, the effects of leakage are only secondary results, due to a primary cause which of itself may cause the stoppage of the steam generator. But a leakage at a joint may in itself gradually cause the destruction of the boiler. Here we see another reason that the character of a boiler, not merely as to ultimate strength, but also as to wear and tear, intimately depends upon the form of its joints. It is often noticeable that very good lap-joints, even when tested under hydraulic pressure up to only 50 per cent above the working load, sweat more or less. The tendency of the internal pressure to form a correct circle bears indirectly on these joints, causing them to open, more or less, and to leak, in spite of the caulking. Mr. Robert Galloway, C. E., who, as an engineer surveyor of long standing of the Board of Trade, has probably made more than three thousand careful inspections of marine boilers, states that he has often noticed a furrow or channel on the outside of the joint, running parallel to the outside overlap for some distance, and evidently caused by leakage. Along the water line, condensed water will act on the joints, while below it the concentrated contents of the boiler will come into chemical action. A leakage in a marine boiler often eats away a plate within a year. In some cases a jet

* Institution of Mechanical Engineers, 1863. Discussion on Mr. James Jack's paper "On the Effects of Surface Condensers on Steam Boilers."

of hot water from a leakage has a frictional action; in fact, even with such an incorrodible and hard substance as glass, an effect like this has been perceived, and a slight leakage continued during several days sometimes produces a noticeable furrow on a glass gauge tube. With sulphurous fuel, a powerful chemical action will come into play on the plates. One volume of water takes up about thirty volumes of sulphurous acid gas; and these sulphurous fumes of the fuel, coming into contact with the water from a leakage, will be more or less absorbed. An acid solution like this must quickly eat away the plate. It is certain that a leakage acts much quicker on a boiler fired with sulphurous fuel than on one fired with wood. M. G. Adolphe Hirn has observed a plate, nearly seven-eighths thick, to be pierced, in the course of time, as with a drill, by means of a little jet which struck it after passing through a current of hot coal smoke.*

CONDENSATION IN STEAM ENGINES.

By M. E. Cousté, Government Director of Manuf. Translated from "Annales du Génie Civil."

(Concluded from page 805.)

It is apparent that, among the causes of the inferiority of the surface condenser, incrustation is one of the most efficient. It will therefore be proper to examine whether there be any method of preventing, or, at least, of diminishing it.

1st. The condensing water, whether derived from wells, from rivers, or from the sea, always contains incrusting salts, such as bicarbonate of lime, in the case of fresh water, and bicarbonate of lime and magnesia in salt water. These salts, losing a portion of their carbonic acid, will deposit neutral carbonates upon *the exterior face* of the condenser, unless they are converted into soluble salts by the addition of sulphuric or hydrochloric acid. But as sea-water, and most fresh water, contains more than .0002 of carbonates, the use of these acids, however cheap they may be, would be very expensive.

2d. As to *the interior surface*, nothing can prevent its incrustation. Indeed, supposing even that the feed water be perfectly distilled, and contain no salt in solution, it will still hold in suspension insoluble matters, resulting from the boiler cements, from the wear of sliding surfaces, and especially from the oxide of iron, which is produced abundantly. The steam, carrying a certain quantity of these substances in a state of minute division, deposits them upon the condensing surface, where they form a crust, which is much aggravated by the lubricants, also introduced by the steam. It would be hopeless attempting to remedy these difficulties by filtering the water after issuing from the condenser, and before injection; this would be merely a palliative, since incrusting matter is constantly forming in the boilers, in the cylinder, and in the steam pipes.

3d. Finally, these substances, supplied by the various members, are by no means the only ones which contribute to the incrustation of the internal face. Practically, it is impossible to make a surface condenser perfectly tight. The extent of surface required necessitates the use of very many small flues (4,000 to 5,000 for an engine of 350 horsepower). In the great number of joints occasioned by these flues, owing to the frequent alternations of temperature, there will always be some leaks, through which the exterior water will be forced by atmospheric pressure. The water in the boiler thus becomes rapidly charged with incrusting matter, which is deposited in crystals of carbonate and sulphate of lime, and, in the case of sea water, of free magnesia.

It may also be remarked that with the cold water entering through imperfect joints, are introduced the gases which it holds in solution, whose presence in the flues of the condenser neutralizes the effect of the vacuum.

4th. The incrustation of the surface condenser is therefore inevitable. But will it be practicable to diminish it by a systematic method of cleaning? In a previous paper on the incrustation of boilers I indicated, in reference to a structure having a close resemblance to the surface condenser, a method of cleaning, which might be applied here. It consists in providing an alternate condenser, thus admitting of the rest of one of them which would allow the application to the exterior of the flues of a weak solution of hydrochloric acid, in order to dissolve the carbonates, and to the interior, of a concentrated boiling solution of carbonate of potash, in order to break down the thick scale and facilitate its removal by means of the ordinary flue scraper.

Having established the general theory of condensation, and deduced the superiority of the injecting over the surface condenser, and having enhanced this superiority by indicating the improvements of which it is susceptible, it remains to demonstrate that it is applicable to marine engines, as well as to other condensing engines, and to describe the method of its application.

The obstacle in the way of condensation by injection in marine engines working at high pressures is not in the principle of condensation, but in the water-supply of the boilers. By the mere elevation of temperature the feed water precipitates its calcareous salts, even without the added effect of progressive concentration, and deposits them in the boiler, partly in the form of scale, which diminishes the transmission of heat, and partly in the form of small crystals, which gather upon the heating surfaces. When the pressure does not exceed 1.5 to 2 atmospheres, or the temperature does not exceed 121°, the point at which sea-water dissolves twice the quantity of sulphate of lime which it contains naturally, blowing out may be resorted to at suitable intervals. This will retard, but will not wholly prevent incrustation. But even this resource is no longer available when the pressure rises to 2.4 atmospheres and the temperature to 127°, since, at that point, the water begins to deposit its sulphate as soon as it enters the boiler.

It is essential, then, to obtain a feed water free, or nearly so, from calcareous salts, and for this purpose the surface condenser was devised as a simple method of obtaining distilled water, which was most reasonably supposed to be eminently suited to boiler supply.

Generally speaking, then, the function of the condenser may be said to consist of two distinct acts: 1st. Transferring the heat of the steam to cold water, thereby condensing the former. 2d. Eliminating from the engine all of this heat, except so much as is returned to it in the feed water. In both forms of the condenser these two acts are performed *simultaneously*, and in the interval of time occupied by two strokes of the piston. But the general performance of the engine requires only that the first act should be accomplished rigidly within the time just mentioned; the other may be effected at leisure with the sole condition, that it be done in such a manner as not to impede the condenser. This state of facts allows the practical application of the *monohydric* principle of condensation, which consists in ejecting into the condenser the same water, continuously and repeatedly, which will be non-incrusting, if previously deprived of its calcareous salts, and in refrigerating it each time it passes the condenser, without intermixture with the cooling water. It is clear that if refrigeration is made a separate operation, entirely independent of the condenser, we shall have all the advantages of injection and a non-incrusting feed water. This principle is not new. It has already been applied to pumping engines in mines where the water is acid and corrosive. I have myself given an application of it in a memoir on incrustation, with the plan of a refrigerator for effecting the repeated cooling of the injected water. I propose to employ it as an accessory of an engine, provided with an injecting condenser, and for a detailed description of it I beg leave to refer to the memoir in the *Annales des Mines* (September and October, 1854). The following is a brief description of the refrigerator:

"The water drawn from the condenser is raised by a pump to a reservoir placed at an elevation of several meters, and underneath this reservoir is located the refrigerator, composed of vertical copper tubes, surrounded by a cylindrical copper shell. The warm water descends from the reservoir through the tubes, which are immersed in the cold water, which is constantly renewed by a current moving from below upwards, i. e., in a direction contrary to that of condenser water."

It is plain that the apparatus employed in the English practice as a surface condenser might be used as a refrigerator, requiring only to be placed in such a manner that the tubes be vertical instead of horizontal, or slightly inclined. The vertical position is essential to a regular and perfect method of refrigeration, since it exposes the descending water to colder surfaces of refrigerating water the lower it descends.

"To avoid the incrustation of the interior surface caused by the lubricants there may be occasionally introduced into the tubes a hot alkaline solution, which will saponify the crust. For cleaning the exterior surfaces of the tubes a process is adopted analogous to the preceding. It consists in introducing into the cold water space a weak solution of hydrochloric acid, which will dissolve the carbonates. By means of a system of suitably arranged valves both operations may be effected promptly, without labor and without deranging the action of the engine."

As to the details of construction, especially the setting of the tubes, their diameter, etc., one could not do better than follow the established rules of English practice for surface condensers.

Although I see no reason to doubt the efficiency and success of the monohydric system of condensation, I think it might be well to examine some particulars of the process. The quantity of heat to be withdrawn from the apparatus, for each stroke of the piston, is $q\ (650-\theta)$. This, obviously enough, is the same quantity which is carried off by the cold water, which circulates around the exteriors of the tubes of the English surface condensers, and, finally, is also the same as that which should be removed from the condensing water by the refrigeration. In the condensers the transmission of heat takes place by virtue of the difference of temperature expressed by

$(a-b)$, and $a=\frac{\Theta-\theta}{2}$, which is greater than θ.

In the refrigerator this transmission takes place by virtue of $(\theta-b)$. This is a disadvantage, as it reduces the rapidity of the cooling; but it will be largely compensated by the absence of air in the tubes, by the regularity of the process, and by the diminution of scale. In brief, the ratio of one sq. meter per horse power, adopted in England for surface condensers, will be more than sufficient for the refrigerator. Were it otherwise it would be easy to increase this surface until the desired effect be obtained. With respect to leakage in the joints, which has been discussed with reference to the surface condenser, we should find the same difficulty recurring in the refrigerator, but only in an immaterial degree; since, on the one hand, the pipes of the refrigerator would be subjected to much smaller changes of temperature, and on the other, there would be no difference between the interior and exterior pressures. Again, the intromission of gas, which is a serious matter in the surface condenser, is of no particular consequence in the refrigerator.

The presence of a small quantity of sea water in the feed water, far from being an evil, will be beneficial. It would cause a slight incrustation, which would protect the plates against oxydation and the deposit of grease. This would add to the conductibility of the metal, provided the scale remain within the limits previously described.

It has been determined in England that, in engines having surface condensers, there is a corrosion due to the grease brought into the boilers by the feed water. This substance accumulates constantly, producing numerous cavities in the plates, thus shortening the life of the boilers and exposing them to the danger of explosion. The English remedy this difficulty by introducing into the feed water a small quantity of sea-water, which gives rise to a slight protective incrustation of the metal. To this precaution some people add another, viz: omitting to lubricate the piston and slide valve, thus extirpating the evil at its source. This mode of procedure is undoubtedly a great sacrifice. Still, it may be necessary in surface condensation, but it is not so in the monohydric system—a consideration strongly in favor of the latter.

It might be feared that the increase of weight and bulk required by the refrigerator would be a difficulty. But, it will be remembered that the refrigerator is merely a surface condenser with a change of function, and the English have found means of placing in vessels of all sizes surface condensers having more than a square meter of surface per horse power. Their experience for the last four years or more ought to reassure us on that point. We may close this paper with a statement of the following general conclusions: There is great advantage in using steam at high pressures in marine engines. Two methods of its application seem to present themselves: 1st, the surface condenser; 2d, the injecting condenser on the monohydric principle. The injecting condenser is, on principle, much superior to the surface condenser; this superiority is expressed by the ratio of the parts of the resisting work, due to the retardation of condensation, in each apparatus respectively,

$$\frac{Tci-p\ S\ L}{Tcs-f\ S\ L} < \frac{\sigma^2}{\Sigma^2} \cdot \frac{R_s{}^2}{R_i{}^2}$$

R_s and σ being always very small as compared with R_i and Σ.

By the injecting system it is possible to reduce the resisting work of the back pressure to $\frac{1}{4}$ of what it is in the actual injecting condenser, supposing the most favorable conditions; conditions which in the surface condenser are ideal, and can never be realized by reason of the friction of steam in the tubes, the presence of air and of incrustations, which are formed within and without.

The surface condenser consequently is subject to perturbations which may deteriorate considerably, and even counterbalance the advantages of high pressure. The injecting condenser will realize these advantages simply and surely. Hence there is good ground for abandoning surface condensation and employing injecting condensation on the monohydric principle.

AIR IN ILLUMINATING GAS.

From a paper in the "American Journal of Science and Art," "On the effect of Atmospheric Air when mixed with Gas in reducing its illuminating power," by B. SILLIMAN and HENRY WURTZ.

The data given in this article were obtained during an investigation of the Hydrocarbon Gas Process by the "*Gwynne-Harris*," or "*American System*," some notice of the results of which we propose to publish in a future number of this Journal. In the course of this investigation it became important to measure exactly the effect of atmospheric air in reducing the illuminating power of gas. Owing to a mechanical defect in the apparatus connected with the exhauster, it was found that a variable quantity of air had for some time found its way into the gas holder, the influence of which, in diminishing the brilliancy of combustion, was sufficiently conspicuous before the cause was ascertained. The only experiments on this subject known to us when its study was undertaken by us, were those of Messrs. Audouin and Bérard* (also quoted in the American Meter Co's. Pocket Almanac). By these results the ratio of loss in illuminating power by the addition of each one per cent of air appeared to us so enormous, that we were desirous of confirming them. Subsequently we became acquainted with an important paper on this subject by Mr. Carl Schultz,† the main points of which are reproduced in this article; as they appear to have escaped attention, the author having modestly given us only his initials, and the journal in which they appeared being almost inaccessible to scientific readers.

* Ann. de Ch. et Phys., 3d series, vol. lxv, p. 423, 1862.

† American Gaslight Journal, Aug. 1, 1860, p. 41.

In conducting this research we soon found that the attempt to introduce, by measure, a given volume of air into the gas holders connected with the photometric apparatus, was attended with many sources of error, and that the requisite accuracy could be obtained only by the eudiometrical analysis of each successive mixture.* The apparatus employed consisted of two gas holders of ten cubic feet capacity each, connected in such a manner that each could be used independently, or the contents of one transferred to the other and back again to secure a complete admixture of the contents. The air was introduced by opening a stop-cock connected with the interior, and adding weights to the counterpoise, measuring the influx by a centissimal scale of equal parts attached to the drum of each holder. This rude admeasurement was controlled by an analysis of each mixture. This required also the prior analysis of the street gas on each occasion, columns 3, 4 and 5, of the accompanying Table I, show the results of these mixtures as made known by the eudiometer. The illuminating power of each sample was determined by the Bunsen photometer on

* Our labors in this research have been greatly aided by the facilities courteously extended to us by the officers of the Manhattan Gas-Light Company, in New York, who with great liberality placed at our disposal their well appointed experimental laboratory and apparatus at their Eighteenth St. Station.

the average of fifteen successive observations of one minute each, with the usual corrections. Columns 6 and 7 give these results, and in columns 1 and 2 will be found the corresponding densities determined by diffusion.

Since the air added in each case is rendered *as gas* by the meter during the photometric measurement, it is important to determine the illuminating power of the gas alone after deducting the known volume of air present. The results of these calculations are given in column 8. In columns 9 and 10, the loss of illuminating power is given; in 8, in terms of the candle power lost for each admixture, and in 9, this loss is stated as a percentage. The ratio of loss of illuminating power in percentage volumes of gas and air is given in column 11, and in column 12 is the loss of power corresponding to each one per cent of air added.

The results of the analyses and photometric measurements are more conspicuously seen in the curve projected from columns 5 and 10 of the table upon the annexed diagram, on which the vertical and horizontal scales are as 1 : 3.

The following inferences depend upon the data herein given, viz:

1st. For any quantity of air, less than 5 per cent, mixed with gas, the loss in candle power due to the addition of each 1 per cent is a little over $\frac{6}{10}$ths of a candle (.611 exactly); above that quantity the ratio of loss falls to $\frac{1}{2}$ a candle power for each additional 1 per cent up to about 12 per cent of air; above which, up to 25 per cent, the loss in illuminating power is as shown by column 12 of the table, nearly $\frac{4}{10}$ths of a candle for each 1 per cent of air added to the gas. In column 11 of Table I, the ratio of loss in candle power is given in percentages for the several volumes, while in column 10 the destructive effect of air upon the illuminating power of gas is most conspicuously exhibited, 12 per cent of air destroying over 40 per cent of the illuminating power. In the diagram this loss of power is represented by the numerals in the right hand column, which are inverse to those in column 10, and stand with the maximum intensity = 100.

2d. With less than $\frac{1}{4}$ of atmospheric air, not quite 15 per cent of the total illuminating power remains; and with between 30 per cent and 40 per cent air, it totally disappears.

Now, during December and January the hydro-carbon gas made at Fair Haven had often as much as 12 per cent of air in it; during the month of February the air, by analysis, averaged nearly 9 per cent; while in March, after the separation of the pump from the exhaustion apparatus, the air was reduced at times to nearly nothing. By column 3 of the table it will be observed that the air found by analysis in the street gas, at the Eighteenth Street Station of the Manhattan Gas-Light Co., New York, averaged nearly 2 per cent, and the New Haven city gas contained about the same quantity. We allow, therefore, this quantity (2 per cent) as a normal amount of air in street gas; and, consequently, in the journal of the daily operations with the hydro-carbon process at Fair Haven,* these corrections have been applied; giving in two columns the "corrected candle power," by the addition of the ratio determined in our Manhattan experiments, and the "corrected volume," or yield per pound of coals carbonized, air being deducted." It is obvious that the records of the station meter give the contaminating air as gas, and without the correction thus obtained, the apparent yield is too great.

In large gas-works the liability to contamination by air accidentally introduced from various causes, diminishes in proportion to the total make of gas, and an amount of air which, when diffused in a very large volume of gas, becomes insignificant, if confined to ten or fifteen thousand feet daily product, will become a most serious injury to its illuminating power. This cause of deterioration in gas has been overlooked almost entirely by gas engineers; but in all small gas-works it deserves special attention, and we have no doubt that the low illuminating power, too often obtained in such works, is largely due to this cause.

Results of Messrs. Audouin and Bérard.—We have already alluded to these results, obtained by Messrs. A. and B., which form part of an important memoir published in 1860, under authority of the French Government "upon the various burners employed in gas lighting, and researches on the best conditions for the combustion of gas." Their table, which we append for the sake of comparison, shows "a considerably high-

* *The Hydro-carbon Gas Process.* Report of working results on a large scale under the Gwynne-Harris Patents, Nov., 1868, to May, 1869, by Benjamin Silliman, M. A., M. D., and Henry Wurtz, M. A., N. Y. 8vo, p. 126, printed for private distribution.

er ratio of loss than we have obtained, being rather more than six per cent loss for each one per cent of air added to the gas, reaching a total loss of 80 per cent with 15 per cent of air added; while we obtain 57.53 per cent loss with 16 per cent; and 93 per cent loss with 20 per cent air, while with the latter volume of air added, we get 72.-90 per cent loss. These differences may be accounted for by the French trials being made upon a gas of not more than 12 candles' power, our trials being made on a gas averaging nearly 15 candles. Also, by the fact that in the French experiments the gas was burned from a batswing burner, ours from a standard Argand.

In the experiments of Messrs. Audouin and Bérard, two gas holders of equal capacity were filled, one with standard gas, and the other with the same gas mixed with 1, 2, 3, etc., per cent of air. Each fed a burner of the second class, regulated to a consumption of 140 liters of gas per hour. The illuminating power of the two were compared by making that of the pure gas equal unity. The results are given in the following table, where each figure gives the mean of 6 or 8 concordant observations.

TABLE II.

Showing the results of mixture of air with gas, by Messrs. Audouin and Bérard.

Common Gas.			Gas mingled with Air.				
Intensity.	Size of flame. Height	Size of flame. Breadth	Quantity of air per 100.	Intensity.	Intensity of loss.	Size of flame. Height.	Size of flame. Breadth.
	mm.	mm.				mm.	mm.
100..........	49	92	1	.94	6	43	102
100..........	48	92	2	.89	11	42	100
100..........	49	93	3	.82	18	42	97
100..........	48	94	4	.74	26	42	91
100..........	46	94	5	.67	33	42	96
100..........	45	93	6	.56	44	41	95
100..........	48	93	7	.47	53	40	91
100..........	48	93	8	.42	58	39	94
100..........	46	94	9	.36	64	39	93
100..........	47	93	10	.33	67	38	89
100..........	46	93	15	.20	80	35	86
100..........	45	92	20	.07	93	33	86
100..........	45	92	30	.02	98	26	79
100..........	45	92	40	.01	99	21	60
100..........	45	92	45	....	100	18	47
100..........	45	92	50	....	100	12	24

By this table it appears that the introduction of 6 to 7 per 100 of air, suffices to diminish the intensity by one half, and a mixture of 20 of air with 80 of gas leaves almost no illumination. Unfortunately Messrs. A. and B. do not record the actual illuminating power of their standard gas, which, however, we are led to believe cannot be more than 12 candles of the English and American standard.

We have already alluded to the experiments of Mr. Carl Schultz, and annex below a summary of his results.

Mr. Schultz concludes from his experiments, that the loss of illuminating power due to the addition of air to gas, is about one-half of one candle for each one per cent of air added. He makes the very remarkable observation, that, within limits, the addition of air to *very rich* cannel gas, up to 12 per cent of air, was followed by no loss of illuminating power, but, on the contrary, by a small gain. Thus, boghead cannel gas, giving for 88 per cent gas an illuminating power of 27.47 candles, or for 100 per cent gas 31.32 candles, with 12 per cent of air, gave 28.29 candles, showing that 12 per cent of atmospheric air had increased the illuminating power of the flame by .82 candles. These results are obtained only by the use of an Argand burner. By substituting an intensity burner for the Argand, the results obtained with gas from boghead conform to the rule of half a candle loss for each one per cent of air. (Rev. Mr. Bowditch also states generally, that "impurities are far less destructive of light in Argand burners.")

Mr. Schultz sums up his results in the following propositions:

1st. When coal gas is mixed with atmospheric air, its illuminating power for all 5 ft. burners is reduced in the proportion of half a standard candle to every 1 per cent of air present, except in case of very rich gas burned with a 15 hole Argand.

2d. One cubic foot of atmospheric air will destroy an amount of light equal to 10 English standard candles, during one hour.

3d. This loss being constant, the percentage of aggregate loss will vary with the illuminating power of the gas used.

While our results confirm in general those of Mr. Schultz, in 1860, and of Messrs. Audouin and Bérard, in 1862; it is obvious that the ratio of loss, with equal increments of air added to a 15-candle gas, is by no means constant. The difficulty of obtaining exact results, by the method of mixture of measured volumes is so considerable, especially with quantities below 10 per ct., that the only safe control of the results is that which is obtained by eudiometrical analysis of the several mixtures tested, as was done by us in all cases both before and after the addition of air. It is obvious that the surprising loss of intensity by the addition to illuminating gas of small percentages of air must be owing not merely to the interior combustion due to the presence of oxygen, but still more, probably, to the associated nitrogen, which acts not only as a diluent, or deductive quantity, but its specific heat is an actual *divisory* function in diminishing the flame temperature. The interesting observation, first made by Mr. Schultz, that in very rich cannel gas there is actually an increase of intensity within certain limits due to the presence of oxygen, suggests another series of experiments with successive additions of oxygen to a gas of high illuminating power, which we propose to undertake at our early convenience, as also another series upon mixtures of progressive quantities of carbonic acid.

NOTE.—*Erdmann's Photometer* (*"Gasprüfer"*) depends on the use of air to destroy the illuminating power of gas. Elster has employed this instrument in a series of researches, undertaken to determine the theoretical illuminating power of different materials ("Journal für Gasbeleuchtung," Munich, 1862, p. 384, *et seq.*) After removing the illuminants by sulphuric acid, he found that ordinary illuminating coal-gas required 150 volumes of air to destroy completely the yellow flame of 100 volumes of gas. If the amount of light obtained by the addition of one per cent of olefiant gas to the decarbureted gas employed in a definite burner, is called *one candle*, it was found necessary to add 6.5 per cent of air to destroy the illuminating power of this gas containing one per cent of olefiant gas, or to destroy one candle power. As a like quantity of carbon, carried to a white heat, produces always, in a gas burning from the same burner, the same quantity of light, and it requires the same quantity of air to transform it into carbonic acid, we may regard an ordinary 12-candle gas as a mixture of an unknown non-luminous gas, holding in suspension during combustion a quantity of white-hot carbon, equivalent to 12 per cent of olefiant gas, and requiring, consequently, a quantity of air equal to 210 volumes for 100 volumes of gas ($88 \times 1.5 + 12 \times 6.5 = 210$). Each additional candle power requires an addition of 5 volumes of air, as the constant indicated by these results of Elster. [*Translated from Schilling, French Edition of* 1868.]

In the use of the Erdmann apparatus, it is found that the volume of air required completely to destroy the illuminating power of coal-gas ranges from 188 to 245 volumes per 100 volumes of gas, varying with its richness.

These results, it will be observed, harmonize in a satisfactory manner with those obtained by us, as embodied in Table I.

Every chemist will at once recur, also, to the action of air upon gas in the Bunsen burner, in constant use in all laboratories provided with gas—an instrument identical in principle with the *Gasprüfer* of Erdmann.

STEEL RAILS.—Certain tests of the ductility of steel rails are about to be instituted at the works of the New York Central Railway, at West Albany. We will try to give our readers the result in our next issue.

THE MECHANICAL VENTILATION OF MINES.

By MR. WILLIAM COCHRANE.

Abstract of a paper read before the Institution of Mechanical Engineers at Newcastle.

It must be admitted that in the great advance which has been made in the development of mining enterprise, and looking to the future requirements of our local coal fields, adequate ventilation is not inferior in importance to any of the problems which the mining engineer has to solve. The earliest records of mining make us acquainted with the readiest mode of ventilation, no provision beyond the natural conditions being adopted; and so long as mines were only worked to a very limited extent by levels or "adits," and if by shafts, of very small depth, the natural system was found to answer all requirements; only there was this disadvantage — that, with thermometrical variations, the determination of the current of air was dependent on the average temperature of the mine being above or below that of the external atmosphere, a condition constantly varying and interchaning throughout the year, and therefore not permitting any certainty of action in the direction or quantity of air which can be used for ventilating the mines. This system is still used in mines of limited extent, and where, from the nature of the mine, very small resistances are offered to the current of air circulating. In some cases, under these conditions, as in the Staffordshire "thick coal" mines, the determination of the air into a particular course is often ensured by placing a fire lamp in the upcast shaft. Such a contrivance, however, can only produce a very small effect, and is therefore of limited application. On a larger scale, however, this principle has formed the most generally adopted system of mine ventilation in this country, namely, that of the furnace. This paper then described the system now most generally in use, and went on—Much discussion has arisen as to the best system of furnaces and the most economical mode of feeding them with air. The following were the results of some recent experiments that had been made at different collieries in the northern coal fields under various conditions and depths of shafts, extent of workings and thickness of the seams of coal, and were reduced for the purpose of comparison to the duty that one pound of coal consumed, effected per horse power on the air circulated in the mine, the pressure being indicated by a water gauge placed in the mine, and therefore representing only the work done in overcoming the friction down to the mine, and exclusive of the work required to overcome the friction resistance of the two shafts. The general result of the experiments was that that duty varied from 37 lbs. to 101 lbs. of coal per horse power on the air taken upon currents of air ranging from 40,000 to 120,000 cubic feet per minute. Depth of shaft, it is said, is the most important consideration for the efficient application of a furnace. There are other conditions, however, which it is necessary to secure, namely: that the shaft be dry, and that it be lined with a good heat-retaining material. It is considered a fair estimate of the economic value of the average conditions in which furnaces are worked that only five degrees of the heat due to the combustion of the coal are utilized. There are many objections, besides the small useful effects in the use of the furnace, which cannot be overcome, and which form a constant source of cost attendant upon it, namely: the necessity of cleaning the flues and the consequent suspension of the active ventilation of the mine; the inconvenience, and in some cases the impossibility, of using a shaft highly heated and often full of smoke, for any other purpose than as a ventilating shaft, and the serious damage done to cast-iron tubing, timber, pumps or wire ropes, where winding is carried on in the up-cast shaft by the products of combustion, especially where the shaft is damp. If the conditions are unfavorable for the use of a furnace—such as shallow shafts and heavy resistances to be overcome—the furnace is then quite unable to compete with a good mechanical ventilation for economical effect. The limit of the furnace as a ventilating power is soon reached where the resistances offered by a mine are heavy; and this objection materially led to the adoption of other means to meet the conditions under which the furnace would fail to afford a sufficient ventilation. Machines for blowing fresh air into or exhausing the foul air from mines were adopted in the very earliest times, especially abroad, where the conditions of the seams are such as required more efficient means than the furnaces supplied. Hence it is that mechanical ventilators are very numerous abroad, while in this country, until very recently, they were quite exceptional. In a table compiled by Mr. J. J. Atkinson, Government Inspector for the Durham coal field, has been shown the depth at which furnaces are estimated to be equal to ventilating machines in point of economy of fuel, assuming that the sources of loss are of the same extent in each case; that is, the loss of fuel in furnaces by cooling in the upcast, and in ventilating machines the power expended in overcoming the useless resistances, and that the ventilating machines utilized 60 per cent of the engine power. The general result is that the minimum depth at which the economy by the two plans is equal is 960 yards, with an average upcast temperature of 100° Fahr., and a depth of 1,130 yards with 200° Fahr. temperature, estimating a consumption of 8 lbs. of coal per hour per indicated horse power of the engine. A recent calculation by M. Guibal, of Mons, deduces the following comparisons: that if a furnace in a 12 ft. shaft, 400 yards deep, circulate 53,000 cubic feet of air per minute under the total resistances represented by $3\frac{1}{3}$ in. water gauge, and an average excess of upcast temperature of 108° above the downcast, with a duty of 31 lbs. of coal per horse power in air estimated upon the total resistances—a mechanical ventilator utilizing 60 per cent of the power employed would, under the same conditions, have a duty of 11 lbs. of coal per horse power in the air, being a saving of 64 per cent. At a depth of 550 yards to circulate the same volume, the duty of the furnace being 22 lbs. of coal, that of the mechanical ventilator would be 11 lbs., being a saving of 50 per cent. The paper then classified the mechanical ventilators which had been used under two heads—first, those working by centrifugal action; and, second, those working as pumps. Of those of the first class, one had been described at the last meeting—the Guibal ventilator, at Crudley Colliery, Staffordshire. The largest example, it went on, of that class erected in this country will be seen at the Thrislington Colliery. It is 36 ft. diameter and 12 ft. in breadth, driven by a horizontal cylinder 30 in. diameter and 30 in. stroke. This ventilator has only been recently erected, and is not yet ventilating any large extent of working, but some experiments have been made with it, from which the following results have been obtained. The regulating shutter was not properly adjusted so as to give the best results of working, and the drift to the upcast shaft was too small for accurately increasing the current of air, amounting to 80,000 cubic feet per minute. With 54 revolutions per minute a water gauge of $2\frac{1}{2}$ in. was maintained at the inlet; with 70 revolutions a water guage of $4\frac{1}{2}$ in., and with 80 revolutions a water guage $6\frac{1}{4}$ in. After giving the results of other Guibal ventilators in operation, the paper continues: In order to make a fair comparison of the Guibal ventilator with the furnace, the following case of the Pelton Colliery, Durham, is given, as it is the only one where the data have been accurately ascertainable respecting the replacing of the furnace by this mechanical invention. In this case the duty obtained by the furnace was 102 lbs. of coal per hour per horse power in the air estimated, on the water gauge of $\frac{1}{10}$ in. indicated in the mine, and a current of air of 35,000 cubic feet per minute; and the duty was reduced by the ventilator to 20 lbs. per hour per horse power with a current of 54,000 cubic feet, and a water gauge of 2 in. indicates in the same position. This shows a saving of fuel by the adoption of the Guibal ventilator in place of the furnace, amounting to 80 per cent. The class of ventilators to which the Guibal belongs is that of centrifugal action, and in the same class may be mentioned the Biram, Nasmyth, Brunton, Rammell and Waddell ventilators. [Diagrams of the Nasmyth, Rammell and Waddell ventilators were exhibited.] A Biram ventilator (similar in principle to the Nasmyth, with the exception of the vanes being inclined to the radius) the writer has experimented upon at Tursdale Colliery, Durham, and found that only $12\frac{1}{2}$ per cent was utilized of the gross power supplied from the steam boilers; and from experience with other open running fans, he considers that percentage cannot be materially exceeded with any form of open fan without a casing. A Waddel ventilator, recently erected at Pelton Colliery, utilizes only 39 per cent of the power applied; and a Rammell, at Framwellgate Moor Colliery, does not exceed 40 per cent of utilized power. The Guibal utilizes 60 per cent of the power applied. Except the Guibal, all the other ventilators of this type discharge throughout the entire circumference; but that this is a defect can be inferred from the fact that if such a fan running open have the access of air into its center stopped, great power will still be required to make it revolve, though no useful work is done. The useless work done upon the external air in this case is done to a diminution of useful effect, when the fan is exhausting air supplied at its center from any mine drift or passage. It was anticipated that the Waddell ventilator would obviate this defect by arranging the air passages through fans of a gradually decreasing section from the center to the circumference, so that the velocity of rotation at any point multiplied by the sectional area of passage at that point should be constant, thus filling up the fan with the issuing air, and preventing the possibility of re-entries. In this case the re-entries cannot be seen as in the Biram, where the eddies of air all round the circumference are easily distinguished, but that they do evidently arise is proved by the lower power utilized. The Brunton, which closely resembles the Waddell and the Rammell, cannot be expected to yield any better results. By the kind permission of Mr. Daglish, the results of a Rammell ventilator, recently erected at the Framwellgate Colliery, are here given: diameter of ventilator 22 ft., with 20 in. steam cylinder and 102 revolutions per minute; volume of air 53,600 cubic feet per minute, with a water guage of $2\frac{1}{8}$ in.; result, 40 per cent utilized. One of the chief reasons of the low useful effect of these exhausting fans is that they are exposed throughout the entire circumference to the external air, which rushes in behind the vanes to supply the vacuum formed by their revolutions; but this vacuum ought to be supplied only from the mine to be ventilated, and it was this consideration, and the practical proof that this injurious effect was inherent in open running fans, that led to the casing of the Guibal ventilators, and discharing the air at only one part of the circumference. This step, however, was attended with the objection that the air was discharged with a high velocity, viz: the velocity of the periphery of the fan, and carried away with it a most important store of force, the partial utilization of which has been effected by adapting the principle of *evased* tubes to the expanding chimney, in which the casing of this ventilator terminates. The air entering its base at a high velocity, leaves the chimney at a reduced velocity proportionate to the increased area of the outlet, and in this action restores a considerable amount of power it would otherwise carry off. An adjustable shutter was next found necessary, in order to regulate the size of the outlet and the various conditions of the volume of air required and resistances. A series of very interesting experiments had been made, showing the steadily improved results obtained from the ventilator, as the casing chimney and shutter, in its accurate adjustment, were consecutively added. Generally, as to the powers supplied from the steam boilers for working these ventilators, 60 per cent was found to be utilized; but it must be noted that this amounted to at least 80 per cent of the power actually transmitted to the ventilator, as one-fourth of the boiler power must be allowed for the loss due to the friction and imperfection of the steam engine. One of the ventilators (of which several examples were now in use in this country of 36 ft. diameter) had been recently started in Belgium of 40 ft. diameter, but detailed experiments had not yet been made upon it. It was arranged to work at the speed of 80 revolutions per minute, producing a ventilation of 150,000 to 200,000 cubic feet of air per minute, under a depression of the water gauge of about 7 in., which was certainly the maximum requirements of any known condition of mines. Indeed there could be no question that any practical requirement in the ventilation of mines could be satisfied by this system, and it could not be surpassed in simplicity of construction, small liability to accident, and the little wear and tear to which its working parts were subject. The paper next pointed out the peculiarities in the Guibal ventilator—as to the concentric form of the casing and as to the curving of the vanes—and it then dealt with the second class of mechanical ventilators—that in which the principle of variable capacities, as in the pump, was involved. Struve's air-pump ventilator was the best known of the class, and consisted of two gasometer-formed pistons working in rings of water, alternate upward and downward strokes drawing air from the mine, and forcing it into the atmosphere by means of suitably arranged valves. The Struve was, when well constructed and in good order, capable of producing a very satisfactory exhaustion, but for certain reasons it did not offer the advantages for mine ventilation which the centrifugal action fan did. The useful effect was from 40 to 45 per cent of the boiler power, when all the working parts, and especially the air valves, were in good condition. In conclusion (to quote the words of the paper) the economy of fuel, if neglected hitherto, has now become of paramount importance. To increase the amount of air in any given time, the mine requires the consumption of an increased quantity of fuel, proportionate to the cubes of the volumes; thus, for twice the volume eight times the fuel. Hence the best system of ventilation is that which, under the same conditions of mine and the same amount of first outlay, produces the maximum work for one pound of coal consumed, so long as such ventilation compares satisfactorily with any other in the points of durability and cost of working, and possesses the quality of adaptability to all the varying conditions which are met with in mining operations.

TESTS OF STEEL RAILS.—Messrs. John A. Griswold & Co.'s circular thus describes their method of testing steel rails:

"1st. A test ingot from each five-ton ladleful of liquid steel is hammered into a bar, and tested for malleability and hardness, and especially for *toughness*, by bending it double cold. In case any test bar falls below the standard established as suitable for rails, all the ingots cast from that ladleful of steel are laid aside for other uses.

"2d. All the ingots, and each rail rolled from them, are stamped with the number of the charge or ladleful. A piece is cut from one rail in each charge, and tested by placing it on iron supports a foot apart, and dropping a weight of five tons upon the middle of it, from a height proportioned to the pattern of rail. A blow equivalent to a ton weight falling 10 to 15 ft. is considered a severe test. We use a five-ton weight falling from a less height, believing that it more nearly represents in kind (although it of course exaggerates in severity) the test of actual service in the track.

"In case a test rail does not stand the blow deemed proper and agreed upon, the whole of the rails made from that charge or ladleful of steel are marked No. 2, and sold for use in sidings, where their possible breaking would do no great harm, and where their greater hardness and resistance to wear would be specially valuable.

"In addition to this double test, the rails are rigidly inspected for surface imperfections.

"We believe that these tests render it practically impossible for us to send out rails of inferior quality.

"We farther invite railway companies to send inspectors to our works to witness the tests mentioned, and other tests and inspections agreed upon."

THE ELLERSHAUSEN PROCESS.—We give elsewhere some interesting details. In a future number we shall describe a modification which will prove of still greater interest.

BOILER EXPLOSIONS.

From a paper on "Government action with regard to Boiler Explosions. A statement of various plans for the object of discussion." Read before the British Association by Mr. LAVINGTON E. FLETCHER, C. E.

It is not in accordance with the rules of the British Association for Reports presented by Committees appointed to investigate and report on certain subjects, to be discussed in the meetings of the Sections. There are circumstances, however, at the present time, that render it especially important that the opinion of the members of the British Association should be fully expressed on many of the questions touched on in the report just read relative to Coroners' Inquests and Steam Boiler Explosions. The Home Secretary stated in his place in the House of Commons very recently that he would do his utmost, in the recess, to prepare a measure for the suppression of steam boiler explosions, so that it is of great importance that suggestions from all parties should be invited on this subject, and that the various plans proposed should be fully considered, so that the whole question may be well sifted. Under these circumstances I have, under the advice of one of the Secretaries of the British Association, prepared a brief secondary paper, on which it will be in order to raise a discussion. After the Report already presented to the Association, relative to Coroners' Inquests and Boiler Explosions by the Committee appointed to undertake that duty, I need do nothing more in this paper than name the points on which it is desired to obtain the views of the members of the Mechanical Section of the British Association.

The constant recurrence of boiler explosions, and the number of lives annually sacrificed therefrom, has aroused public attention to this subject. The public begin to suspect that these disasters are not so accidental as it has for a number of years been attempted to make out, but that they might, after all, be prevented. The system of periodical boiler inspection has proved itself sufficient to accomplish this task, and therefore the public naturally ask—why do not all steam users have their boilers inspected, and if they neglect this simple precaution, which has now been adopted by so many for the last fourteen years, why should not the law step in and compel them to adopt it?

This, therefore, opens the first question, whether it is expedient or not for the Government to interfere in the matter of the prevention of steam boiler explosions, and if so, in the second place, what would be the best mode in which the Government action should be taken. In answer to this second inquiry there are at least three plans now before the public, of which a brief outline may be given.

One of these plans is that the Government should take the supervision of every boiler in the country, with the exception of locomotive and marine, and through the medium of the Board of Trade should test all new boilers, and periodically examine them when set to work, as well as all others already in use, the examinations being made both when the boilers are at rest, as well as when at work with steam up.

All Englishmen have a strong dread of Government interference, and of the introduction into this country of the continental paternal system, fearing lest it should hamper progress and fetter individual action. This measure therefore is one which, to say the least of it, is calculated to provoke considerable opposition.

Another plan is, to render inspection compulsory, but not that the Government should take the task of examining boilers into its own hands, that is to say, it is proposed that no steam user should be allowed to work a boiler that had not been examined and certified as safe by some local inspection association or insurance company, duly authorized by the Government as competent to the task.

This plan has certainly less of the air of the continental paternal system about it, and appears more adapted to the usages of this country, though it by no means appears to be free from difficulty in its application. It is important that the integrity of the inspections should be preserved, and it may be well to suggest for consideration, whether there might not be a difficulty in securing this if the question of deciding on the safety of all the boilers in the country was handed over to a number of competing joint stock companies. Joint stock companies clearly exist for the sake of dividends, and it is difficult to see, if they are to be paid by steam users for granting certificates for the safety of their boilers, how the integrity of those certificates could be secured under a pressure of competition for business. Judges, to be impartial, should not be remunerated by those whose cases they have to adjudicate, more especially if their payment depends on giving satisfaction. It is feared that under such a system, inspections might grow lax, and that the sale of certificates would soon be not unlike the sale of indulgences in days gone by. It is therefore a point for discussion how far it would be wise to commit the safety of all the boilers in the country to the charge of commercial competing companies intrusted with the monopoly of the sale of boiler certificates. Possibly there may be some way of meeting this difficulty, but it was thought well to throw it out for discussion on the present occasion.

A third plan is that every steam user should be left perfectly free to lay down what description of boiler he may think best, and to enrol it or not, either with a Boiler Inspection Association or Boiler Insurance Company as he sees fit, and, indeed, that he should be free to do just what he likes as long as he does not burst his boiler, but in the event of explosion it is proposed that the Government should then step in, make a most searching investigation of the facts, and publish the information for the benefit of the community at large. On this system the steam user would be left perfectly free in his choice of means, but would be held responsible for results, and, in the event of explosion, would be open to a claim for damages from relatives of those killed by the failure of his boiler. This plan, it is argued, would act preventively, inasmuch as it would, it is hoped, arouse to suitable vigilance all those connected with the use of steam, which is all that is required for the prevention of steam boiler explosions.

These are three of the principal plans now before the public. The first proposes to act on the paternal system, and to take every boiler under the Government wing. The second does not propose that the Government should undertake any inspections itself, but that it should leave them to duly authorized local associations, rendering it, however, compulsory that the steam user should avail himself of one or the other of these organizations. The third plan goes on the principle of believing every man innocent till he is proved guilty, and of punishing offenders in the hope that by so doing a repetition of the offense by others will be prevented.

Such is a brief recapitulation, and but little more, of the measures now before the public, while the few suggestions that have been added to this brief recapitulation have been thrown out more to stimulate discussion than by way of advocacy in the case of either plan, and full discussion is now invited on these questions from the members of the Mechanical Section of the British Association.

ON CANTING RAILS.

By W. Airy.

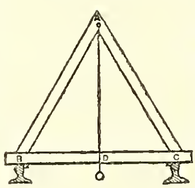
From "The Engineer."

It will generally be found on railways that the amount or cant on curves which the outer rail receives is considerably less than the theoretic cant due to the highest ordinary speed maintained on the line. Nevertheless it is maintained in works on civil engineering that the full maximum cant which the formula demands ought to be insisted upon. Now, when experience has led to a universal system of departure from theory, it may safely be affirmed to be practically correct, and the writer had abundant opportunity of investigating the question. There are two important reasons why the cant should be kept under rather than over the cant due to the highest ordinary speed on the line. First, because a train goes more steadily round a curve when bearing constantly and firmly against the outer rail; and secondly, because when bearing hard against the outer rail, the coning of the wheels assists the motion round the curve. Now, with regard to the first of these reasons, it is well known that nothing tends so much to make engines run off the line as allowing play between the rails. So long as the wheels run steadily and closely between the rails, the train is safe, and it would require a vast force to make it leave the metals; but when the engine has leave to play between the rails, it begins to roll and oscillate from side to side, and has a tendency to mount the rails and leave the line. So well is this known that at crossings, where great steadiness is required to avoid injury to the points of the crossing, it is customary to reduce the gauge to the extent, in some cases, of ⅜ in. Now, on a curve, if the cant be not too great to permit it, the centrifugal tendency will ensure the steady bearing of the wheels against the outer rail, and the train will run steadily round; but if the cant be rather too large for the speed, the engine will acquire a violent oscillatory motion—it will fall off from the outer rail and come upon the inner; then in consequence of the inequality of the lengths of the outer and inner rails, aggravated in this case by the coning of the wheels, it will be thrown back upon the outer rail, and so on. The above would, of itself, form a very sufficient reason for keeping the cant less than that due to the highest ordinary speed on the line; but if the wheels are coned as they usually are, it would seem quite suicidal to cant the rails so much as to throw the pressure upon the inner rail; for then the larger circumference of the wheel would be running upon the inner rail, and consequently upon the shorter curve; the engine would in consequence receive a violent twist and be thrown against the outer rail with its front not tangential to the curve, but sensibly inclined to it, and the tendency to mount the rails would be very great. For both the foregoing reasons it would appear advisable in all cases to keep the cant rather below than above that due to the highest ordinary speed on the line, and the practice of engineers in so adjusting the cant is fully justified.

There is a special difficulty in correctly applying the cant at the commencement of the circular curve. The reason is that the curve commences abruptly, and so, in consequence, ought the cant to commence abruptly. When an engine passes off a piece of straight upon a circular curve, it is suddenly exposed to the full centripetal force due to that curve; the effect of this is to give the engine a sudden jerk, similar to a blow, and tending to twist the engine round in the direction of the curve. The effect of this twist, however, remains unbalanced, and prevents a repetition of such shocks as the engine passes along the curve; and if the rails be not overcanted the motion is as smooth as on a piece of straight. But it is impossible to apply the cant suddenly, as the curve is applied; and to apply the cant gradually on the piece of straight leading up to the curve would have the dangerous effect of making the engine roll and oscillate as already described. So that there seems to be no proper remedy for this inconvenience, except by flattening the curve at the commencement, either by eye, in the manner of platelayers, or by the use of easier and more gradual curves than the circular curves which are usually adopted.

There is an important question suggested by the numerous girder bridges on the Charing Cross Railway. Some of these, at Southwark-street and London Bridge, are on sharp curves, and the question arises, Ought not the girders that carry these bridges to be canted? Evidently they ought. The girders are subjected to two forces: one a vertical force due to the weight of a train, the other a horizontal force due to the centrifugal force of the train on the curve. The combination of these two forces give rise to a resultant force inclined to the vertical, and the girders, in order to meet this force fairly, should be also inclined to the vertical. This inclination is by no means insignificant in amount; it corresponds, indeed, to the inclination of a straight edge laid across the rails to the horizontal, when the rails are properly canted; and this on a girder 12ft. high would appear very considerable. Without, however, insisting upon the full inclination due to the centrifugal force, it is quite certain that a considerable degree of cant might be advantageously applied to the girders on curves; and it is, at all events, to be borne in mind that if a girder be not canted at all, or only moderately canted, an engine passing along the curve at a high rate of speed puts a far greater strain upon the girder than if it passed at a slower rate; and this strain attacks the girder in its weakest point, viz: its tendency to buckle. Such girders should, therefore, be amply stiffened by lateral plates and angle irons.

It is often necessary to check the amount of cant which the platelayers have given on different curves along a considerable length of railway, and for such purposes it is useful to have an instrument adapted to the rapid measurement of the cant. The writer adopted the following method:—A B C is a symmetrical triangular framing of strong wooden laths; B C is the gauge 4ft. $8\frac{1}{2}$ in.; and A D, the perpendicular from A upon B C, is also 4ft. $8\frac{1}{2}$in. From the point A is suspended a plumb-bob, and the rod B C is graduated both ways with inches and parts starting from the point D as zero. Thus, if there be no cant on the rails, and, consequently, their tops are at the same level, the plumb-line cuts B C at the zero point D; and if the rails are canted, then, since A D is equal to B C, the deflection of the plumb-line in inches from D will be equal to the cant on the rails, and the cant can be read off rapidly from the rule itself.



THE REPORT of the State Engineer of New York on Railways, is just out.

THE RESISTANCE OF ARMOR PLATES.

A paper on the Penetration of Armor Plates with Long Shells having Large Bursting Charges, fired obliquely, read before the British Association, by JOSEPH WHITWORTH.

At the meeting of the British Association at Norwich last year, I contributed a paper to the Mechanical Section "On the Proper Form of Projectiles for Penetration through Water." This paper was illustrated by diagrams showing the effects proper on an iron plate, immersed in a tank of water by projectiles with flat-hemispherical and pointed heads.

In that paper I claimed for the flat-fronted form of projectiles made of my metal three points of superiority over the Palliser projectiles adopted in the service.

1. Its power of penetrating armor plates even when striking at extreme angles.
2. Its large internal capacity as a shell.
3. Its capability of passing undeflected through water and penetrating armor below the water line.

This latter feature was, I think, satisfactorily proved by the experiments described last year, and I now desire to draw the attention of the section to the experiments I have made for illustrating the penetrative power of long projectiles with the flat front, fired at extreme angles against iron plates.

These experiments are illustrated by the projectiles actually fired, and the plates they penetrated, which are laid on the table.

The gun from which all the projectiles were fired is called 3-pounder, though capable of firing much heavier projectiles; it weighs 315 lbs. and the maximum diameter of its bore is 1.85 in.

The charge of powder used in all cases was 10 oz., and the weight of the 6 diameter projectiles is 6 lbs.

No. 1 is a portion of a plate 2 in. thick, penetrated by the 6 diameter flat-fronted projectile, at an angle of 35°.

No. 2 is a similar piece of plate 1.7 in. thick, completely traversed at an angle of 45° by the flat-fronted projectile No. 2, which buried itself to a depth of 30 in. in a backing of iron borings.

No. 3 is a piece of plate 1.75 in. thick, penetrated at an angle of 65° by the flat-fronted projectile No. 3.

No. 4 is a plate 1.7 in. thick, nearly penetrated at an angle of 45° by the $3\frac{1}{2}$ diameter flat-fronted projectile No. 4.

No. 5 is a plate $1\frac{1}{2}$ in. thick, against which the *pointed* projectile No. 5 was fired at an angle of 45°. The projectile failed to penetrate the plate, being deflected by the pointed form of bend; the distortion of its shape shows the force with which it struck the plate, and proves the excellent quality of the material which could resist such a test.

No. 6 is a plate also $1\frac{1}{2}$ in. thick, against which a Palliser projectile $2\frac{1}{4}$ diameter long made of Pontypool white iron, with the *pointed* form of head, has been fired; the projectile has scooped out a furrow 4 in. long and $\frac{7}{10}$ in. deep. It broke up into fragments.

The plates Nos. 1 and 3 were purposely thicker than the projectiles could quite pass through, in order that the "work" of the projectiles might be as severe as possible; an examination of the projectiles themselves will show how well they have withstood the severe strain to which they have been subjected.

The data thus obtained fully establish, I think, the superiority I claimed for the flat-fronted projectiles made of my metal, and satisfactorily prove:

1. That the flat-fronted form is capable of piercing armor plates at extreme angles.
2. That the quality of the material of the shell enables their length to be increased without any risk of their breaking up on impact, and thus increases their capacity as shells.
3. That this increase in length, while adding to the efficiency of the projectile as a shell, in no way diminishes but increases its penetrative power.
4. That the amount of rotation I have adopted in my system is sufficient to insure the long projectile striking "end on," and thus to accumulate the whole effect of the mass on the reduced area of the flat front.

These experiments show, further, that the Palliser projectiles fail to penetrate when striking at an angle, solely on account of the form of the head; the Whitworth projectile, which resisted the shock and did not break up, being deflected in precisely the same manner as the Palliser projectile which was shivered into fragments.

The objections I made in my paper last year to the Palliser projectile—1st, that its form of head causes it to glance off, and, 2d, that the brittleness of its material causes it to break up on impact—I have now proved to this section.

The facts illustrated by these experiments are not of recent discovery. Ever since 1858, I have experimented upon and advocated the flat front. I have on the table a small plate, ½ in. thick, experimented upon in 1862, with hardened steel bullets fired from my small-bore rifle. No. 39 is the hole made by a flat-fronted bullet, which has penetrated the plate at an angle of 45°. No. 40 is the indent of a hemispherical headed, and No. 40 of an ordinary round-nosed bullet, both fired at the same angle of 45°. These three rounds were fired in 1862.

Within the last few days I have had a Palliser shaped bullet fired on the same plate at the same angle, in order to compare the effect produced on a larger scale on plate No. 6. It is interesting to observe how closely the effects obtained with the small calibre of the rifle agree with those of the 3-pounder gun, which form the subject of this paper.

These experiments were made with a gun of small calibre from considerations of economy and convenience, but I have always found that what I could do with the smaller calibres of my system could be reproduced in the larger sizes, and from my past experience I feel warranted in asserting that the effects of penetration now exhibited could be repeated on a proportional scale with my 9 in. guns at Shoeburyness, or with 11 in. guns my firm are now engaged in constructing.

A glance at the formidable nature of the projectiles thrown by these guns, and a consideration of the effects they may be expected to produce, will show the importance attaching to the question of penetration of plates by long projectiles.

The 9 in. guns, to which I have referred, weigh 15 tons each, and are capable of firing powder charges of 50 lbs.

A 9 in. Armstrong shell, five diameters long, weighs 535 lbs., and will contain a bursting charge of 25 lbs.

I have no hesitation in saying that these projectiles would pierce the plated side of a ship, at a distance of 2,000 yards, and at some depth below the water line.

The 11 in. guns will weigh 27 tons each, and will be capable of firing 90 lbs. powder charges.

The 11 in. shell, five diameters long, will weigh 965 lbs., and will contain bursting charges of 45 lbs., and would pierce the side of the ship Hercules, plated with 9 in. armor, at a distance of 2,000 yards.

Were it not that the increased destructiveness of war must tend to shorten its duration and diminish its frequency, thus saving human life, the invention of such projectiles could hardly be justified; but believing in the pacific influences of the most powerful means of defense, I have named these long projectiles the "*Anti-war*" shell.

The principle I have always insisted upon, and laid down for my own guidance in artillery experiments, when either a low trajectory or penetration is required, is "*that every gun should be capable of withstanding the largest charge of powder that can be profitably consumed in its bore.*"

I have drawn up a table of the sizes of the bores of my guns, with their proportionate powder charges, and can undertake that they shall be fully equal to this duty, and realize the highest possible consumption for a given quantity of powder.

But the guns adopted in our naval service are not equal to such a test, nor, as I believe, are they so proportioned as to realize the best effect from the quantity of powder they consume.

Four guns of 12 in. bore have lately been put on board the Monarch; they weigh 25 tons each, and fire charges of from 57 lbs. to 67 lbs., and projectiles of 600 lbs. weight. I have no doubt that these guns have been made with all possible care, and are as strong as their material and construction admit of their being; but if the weight of these guns was in proportion to the capacity of their bore, and the material were the best that our metallurgical skill could supply for such a purpose, they ought to fire 117 lbs. of powder, and projectiles of 1,250 lbs. weight. These would then be indeed efficient weapons, but at present they are more formidable in name than in reality. We are often flattered by being told that we have the best guns in the world. That may or may not be the case; but I think we should not rest contented while we are still so far from having attained all that our present advancement in mechanical and metallurgical science has rendered possible to us.

IRON RAILS.—We hope to be able to present to our readers in the next number, a *proof*, drawn from the experience of one of our leading railways, that good iron rails can be produced by paying a reasonable price. There purports to be a doubt on this subject in the minds of our railway managers, but we believe that they have not had an opportunity to familiarize themselves with the facts—and these we hope to present in convincing shape.

IRON AND STEEL NOTES.

The Pomeroy Patents.—The Pomeroy Patents Company possess the following patents for the improved manufacture of Iron and Steel:

1st. For the smelting and refining of Iron in the blast, cupola, puddling, or other furnaces, by the combination of hydrogen in the shape of steam or water, with Franklinite or zinciferous ores.

2d. For the manufacture of cast-steel from the refined iron.

3d. For a hot air double reverberatory furnace for the manufacture of steel or balling up steel sponge.

4th. For a desulphurizing, deoxidizing and carbonizing furnace for making steel sponge.

5th. For an improved method for manufacturing imitation Russia Sheet Iron.

6th. For covering iron with copper or other metals, such as bolts, spikes, nails and sheets.

7th. For movable grate bars for the steel and sponging furnaces, so as to keep the grates clean without opening the doors.

The great advantage of the hydrogen process for the purifying of iron has been abundantly proved. But the chief object since the foundation of the Company has been to demonstrate their steel patent for making steel suitable for rails. For this purpose they erected a furnace at Newark, N. J., which proved of remarkable power, melting old iron rails, refining, carburizing into steel, and casting the ingots in from $2\frac{1}{4}$ to $2\frac{1}{2}$ hours from the time of charging the old rails. Some very fine ingots of steel were produced, which were proved and tested in Philadelphia, to be of superior quality. The work was done in the presence of many experts and other parties, who all expressed themselves satisfied with the results. The irregularity of the old rails and the difficulty of getting a material for the bottom of the furnace to stand so great a heat, were the principal difficulties encountered; but the managers are fully persuaded that these objections will be overcome and the process become a success when a new and improved furnace is erected and a material proper for lining obtained. While making these trials, parties applied to have steel sponge worked in the furnace to try to convert it into steel direct. After many trials it was found to be impossible on account of the great quantity of slag made from the sponge; but it was found that the furnace had superior powers for extracting the iron and that it could then be rapidly balled up into malleable iron, requiring only hammering to make superior blooms for converting into steel, rolling into rails, or other purposes.

The result being so satisfactory, the next requisite was to get a sponging furnace that would do the work thoroughly, expeditiously and cheaply. In this the managers think they are successful, having reduced the time of sponging the crushed ore to about 3 hours, or working continuously 3 heats in 24 hours. This process formerly required ten to twelve days, and the time has been gradually shortening. With improved furnaces, they will be able to reduce the time to six hours, or 6 heats in 26 hours. By these improvements the manufacture of rails can be reduced from $10 to $15 per ton, according to facilities for obtaining coal and ore. The quality will also be very superior to the iron now used for rails, and by proper care in balling up, a small percentage of carbon may be left in the bloom to form the head of the rail, thus making it but little inferior to a steel headed rail. Another great advantage, and a very important one is that the expensive blast furnace will be dispensed with, and works to turn out an equal quantity of blooms, can be erected for about half the cost of furnaces to turn out an equal quantity of pig iron. The furnaces are all so simple in construction and working that there is no great risk of any serious accidents, and only a moderate degree of wear and tear; thus avoiding the great peril of blast furnaces; also the time for erecting works to make blooms, would not be but half the time required to erect blast furnaces. At the experimental works at Newark, magnetic 60 per cent ore has been worked. The balls made were hammered and rolled at Trenton, into a rail 28 feet long, 68 lbs. to the yard, weighing 626 lbs. This rail has been pronounced by all who have seen it, as of superior quality and finish. A piece of the head from the waste end of the rail, has been tested by Whitney & Sons, Philadelphia, for tensile strength, as follows:

No. 1, piece tested	66,712 lbs.,	per square inch.
2, "	66,850 "	" "
Average,	66,780 "	" "

This is 25 per cent stronger than common rails, and ten per cent stronger than the standard for bridge iron.

The ore was good, but had $1\frac{1}{8}$ per cent of sulphur and $\frac{1}{2}$ per cent of phosphorus in it, and yielded 50 per cent in the balls. The great strength is mainly due to the fluxes used in the sponging and balling, together with the use of hydrogen and Franklinite, which eliminate the impurities and make a neutral iron; being so pronounced by an experienced smith.

The refuse of hematite or "slack," has also been sponged and balled, yielding 34 per cent. An ore containing 6 per cent of titanium, has been balled and will no doubt hammer well.

These trials indicate that all kinds of ore can be well worked by the Pomeroy processes. Also that ores too sulphurous or refractory to be worked in the blast furnace can now be utilized. The process also saves at least one ton of coal in making a ton of blooms from the ore, compared to the blast and puddling process for blooms. Pea coal, or fine bituminous, answers for sponging.

The Utilization of Waste Gases from Blast Furnaces.—The blast furnace proprietors who have adopted one or other of the different methods employed for bringing down the gases report satisfactorily of the result. This with regard to one plant of furnaces is seen in the circumstance that between 250 tons and 300 tons of fresh drawn slack heretofore required in raising the steam for their blowing engines and for heating the blast is now being offered for sale. The concern is that of the Parkfield Iron Company at Wolverhampton. If the practice should be extended throughout the whole of the district, and the proportionate saving equal to that here stated, a large amount of economy will have resulted; for notwithstanding that in some cases the adaptation even of the least expensive method is regarded as costly, still the ultimate saving is very marked. Speaking of this one case in particular, the saving may be put as equal to the developing of 500-horse power out of nothing!

Iron and Steel—A New Blast Heating Apparatus.—Homer Hamilton, Esq., of Cleveland, has invented a new blast heating apparatus which, if it performs all that is claimed for it, will prove valuable to furnace owners. The apparatus consists, first, of eight or ten large pipes, divided by means of a horizontal or inclined partition into two chambers, of which the upper one opens at one end and the lower at another. Upou each of these base pipes are eight upright pipes, opening into the upper chamber of the base pipe, and closed at the top. Inside of each of the upright pipes is a smaller tube, opening at one end into the lower chamber of the base pipe, and at the other into a chamber at the upper part of the outer upright pipes. The object of the invention is to construct a simple and effective device for heating the air that is carried into a blast furnace, and consists in the above arrangements of pipes, so that the air will be exposed in thin sheets to heated surfaces, and expansion and contraction will not injure the apparatus. Its operation will be as follows: The burning gases will surround the upright and base pipes, and will heat their surfaces. The air is forced into the lower compartment of the base pipes, thence it passes up into the inner tubes to the upper part of the upright pipes, which are rounded, enlarged and depressed in the center for the purpose of facilitating the transmission of air from the inner tubes to the outside upright pipes, and to avoid friction. The air then passes down the upright pipe outside the inner tube, exposed in a thin sheet to the heated pipe, and is thence transmitted to the upper compartment of the base pipe. It then goes into the blast furnace, or to another heating apparatus of similar construction. It must be understood that for a blast furnace of usual size a series of eight or ten base pipes with their upright and inner tubes, should be provided in order to have a sufficient heating surface. The pipes all support themselves, and cannot strain any supporting frame or other machinery. For that reason a much greater degree of heat can be obtained—a very desirable thing in blast furnace economy. The points of the invention are: First. The arrangement of base pipes and uprights so that the air to be heated will pass from one compartment of the base pipe through all the verticals into the other compartment. Second. The rounded enlargement on the upper end of each upright pipe to prevent friction of the air. Third. The construction of the apparatus so that the air is exposed to the heated surface of the outer upright pipe in thin sheets, and is therefore uniformly heated.—*Pittsburgh Commercial, Aug.* 7.

Special Method of Blooming.—We have lately examined a modification of the Catalan process in the old form of the forge-hearth, at the Logan Ironworks, Bellefonte, which is extremely simple and direct, resulting in the forming of, commercially speaking, an almost absolutely pure iron. The furnace is a few inches above the general floor of the forge-house, and the size about large enough to make one bloom of 200 or 225 lbs. It is about three by four feet, the long way running back from the workman. The instrument for turning, lifting, and aggregating the iron is called a "furgeon," and answers to the rabble of the ordinary puddling furnace. The waste heat passes up and through a chamber immediately over the forge-hearth, where the pigs are placed which become red hot before they are ready to be drawn down upon the bed of charcoal previously prepared. The pigs thus drawn down upon the charcoal bed are covered and the blast turned on into both tuyeres right and left. After a few minutes the iron begins to melt; it is decarbonized by the blast, is worked into shape by the furgeon, and then lifted up clear of the bed and laid upou the top of the same bed again, some additional charcoal put around, and the blast turned on. The iron now is melted in what is called the sinking process, wherein the iron drops through the coal into the hearth until entirely passed into the hearth; there it is again agglomerated into the ball, or "loup," by the furgeon (pronounced *furgun*), the blast having previously been turned on fully; it is then lifted out a balled loup and carried to the hammer. The cinder is tapped off through a hole in the front iron plate, and is rich in iron, with so much silex that it easily emits sparks when the penknife blade is struck against it. Of course, this process is attended by a large loss of iron, while the loup, which gives rise to the cinder, is not thereby improved, as in the puddling furnace. But in this particular instance the iron is singularly pure, and the blooms command $85 per ton at the forge. One ton and a half of pig yields 2,464 pounds of bloom. The charcoal furnace yielding the iron is nearly adjoining the bloomary.

This furnace is only 32 feet high, about 26 inches across the tunnel-head opening, 8½ feet bosh, and the slag is allowed to flow out from the hearth whenever it rises above the fore hearth. The breast is covered with a simple plate of iron; the cinder is always in sight; as soon as the iron appears, the crucible, or tapping-hole, is opened and the iron is tapped off into iron moulds. There are three casts per twenty-four hours, two tons per cast; 150 bushels hard coal (18 pounds to the bushel) to the ton made. Charges, 700 to 750 pipes ore (brown hematite), 27 bushels charcoal, 80 pounds gray limestone of good quality; pressure, a half to three-quarters of a pound per inch; nozzle, two and a half; two woodeu blowing cylinders worked by water-wheel. Some finery cinders, about thirty to forty pounds, are added to the charges and said to improve the iron, which at present, May 26th, 1869, is all forge iron, and used at Stewart & Co.'s wire factory, and reported as a very fine iron.

This bloomary process is interesting as an example of blooming from pig iron, and is the same process spoken of in a certain United States report, if we mistake not, as not existing in this country.—*American Exchange and Review.*

Increasing Exportations of Iron and Steel from England.—It has been shown says the "Engineer" that, notwithstanding all the outcry which has been raised of late years as to foreign competition, the exports of iron and steel from the United Kingdom attained a larger total in 1868 than in any former year. The quantity and value of the exports since 1859 is as follows:

	Tons.	Value.
1859	1,465,191	12,314,437
1860	1,442,045	12,154,997
1861	1,322,649	10,326,646
1862	1,501,451	11,365,150
1863	1,640,949	13,150,936
1864	1,502,964	13,310,848
1865	1,617,509	13,471,359
1866	1,683,390	14,842,417
1867	1,882,650	15,050,391
1868	1,945,246	15,021,907

Malleable Cast Iron.—For the production of this material most of the German founders use first fusion pig, free from sulphur and phosphorus, or Scotch pig. Styria also furnishes a suitable iron which can be used only in the north of Germany, however, on account of the expense of transportation and high duties. On account of the competition of wrought iron, great cheapness is very essential to its sale. The makers keep secret the brand of iron which they employ, but it is well understood that the brands are not the same in different establishments. The iron is melted in plumbago crucibles, holding about 30 kilog. They are covered with porcelain lids, to keep out impurities and cinders which reduce the high heat requisite for the process. The fire in which the crucibles are placed is from 630 m. to 940 m. square, and is surrounded with bricks of porcelain earth. The use of blast is not advantageous, since the economy of time is offset by a greater consumption of coke. The natural draught of the chimney is sufficient when the furnace is properly constructed. An essential condition of success is a high heat at the moment of pouring. Practice enables the caster to estimate the heat of the furnace, and he recognizes the precise moment by plunging a bar of red hot iron into the crucible, from which, upon being withdrawn, the metal flies off in sparks. The crucibles are raised with tongs with curved jaws, and the pouring is done with all possible speed—the surface being first cleaned. By cementation the casting acquires the properties of wrought iron, having some analogy to steel. The operation consists in subjecting the castings to a prolonged red heat in a bath of pulverized red hematite. They are arranged in boxes of cast iron called muffles. These are square, and with air-tight covers. In arranging the castings in the boxes they are placed in layers alternately with layers of hematite. The cementing furnace is very simple. The grate is in front, and the draught of the chimney carries the hot air around the boxes. The heat should be conducted with care, starting rather vigorously, in order to reach the desired temperature quickly; then supplying the furnace at regular intervals. The cementation lasts three, four, and five days, according to the size of the pieces. A charge is about 350 to 450 kilog. of castings. In arranging the charges large pieces should not be mingled with small, and those muffles containing the larger pieces should be placed in the furnace first. On the other hand, the smaller objects are placed on the sole of the furnace. Without these precautions many pieces may be burned, or badly decarburized—the latter becoming something intermediate between iron and steel. When the operation is deemed complete the fire is allowed to fall, but the furnace is not uncharged until it has gradually cooled. Practice plays an important part in the management of the firing, as the temperature can be judged of only after prolonged experience.—*La Génie Industrielle.*

Improvement in Rolling Iron.—A new description of roller, to be employed in the manufacture of iron plates, bars, tubes, &c., has just been invented by a roll turner, named Robert Robertson, who is at present employed in the Coatbridge Iron Works, the property of Messrs. Martin & Son. The invention, if it succeeds as well as it at present promises to do, bids fair to completely revolutionize the system of rolling, as the new machine possesses so many advantages over the one at present employed. The invention consists of having the rolls tubular, instead of solid as at present, with a stream of water introduced inside of the rolls. The advantages are said to be that the new rolls are from 7 to 8 cwts. per ton lighter than those in use at present, while the water inside the rolls prevents the heated iron from due expansion, while undergoing the process of rolling, and saves a great amount of drag upon the engine. The saving in this respect will be better understood when it is stated that in the item of brass bearing alone the amount of mean steam saved by the new invention is at least 15 per cent. No steam arises from the rolls while working, so that the workmen can pursue their avocations with greater ease and facility. No scales stick to the rolls, consequently the finished bar or plate presents a finer surface. The new roller will also last much longer than the solid rolls, while the chances of sudden breakage are reduced to a minimum.—*North of England Coal and Iron Trades Review.*

Siemens' Open Hearth Furnace.—Mr. Siemens informs us that the cost of the production of steel made in his open hearth furnaces, depends upon the cost of the materials, pig-iron, scrap and the cost of the labor. The following, however, is the cost of production in England, viz: for a charge of *four tons, three* such charges being made in 24 hours in each furnace.

10 cwt. pig-iron.
3 tons 10 " scrap steel.
8 " spiegeleisen.
2 tons ...... coal.

Labor—five men (melter, assistant melter and three laborers.) Repairs, interest, management and royalty. This made the actual cost of the steel ingots £5 10s. per ton.

The cost of one of these furnaces here, with gas producers and all equipments, such as ladle, tramway, etc., would be about $14,000.

As to the durability of the furnace, the best evidence is contained in a letter from Mr. Siemens, dated February 16, 1869. He writes, "you will be interested to learn that the manager of the Bolton Steel and Iron Works (Mr. Webb), has told me that his furnace crown (open hearth steel melting) has stood 70 charges, and looks as good as new. At the lowest computation the furnace will last 100 charges, and the cost of repairs will amount to less than *one shilling* per ton of steel melted."

We quote again from a late letter of Mr. Siemens—"These furnaces are now in regular operation at Swansea, Bolton and Crewe, where first class steel is made by them; that made at Bolton having been tested by P. W. Barlow, Esq., F. R. S., on behalf of the Institute of Civil Engineers, who are desirous of establishing 'standards for the employment of steel in construction,' was found superior in tenacity and ductability even to crucible steel, and far superior to Bessemer steel."

We copied a paragraph which appeared in "Engineering" in reference to Mr. Samuelson of Middlesboro', England. We learn from an authentic source that it is quite true. Mr. Samuelson has ceased to manufacture steel according to the "Siemens-Martin" process, but his failure must not been held to affect the process, as he did not work according to Mr. Siemens instructions, but allowed himself to be guided by M. Martin, who was unacquainted with English irons, and he also followed his own notions. Moreover he had no chemist and consequently was working in the dark.

CLEVELAND IRON MAKING.—It seems but a short time since, and it is in reality less than three years, when the furnaces in the Cleveland district were making about one million tons of pigs yearly. Notwithstanding the depression in trade they are now reported to be turning out iron at the rate of 1,400,000 tons yearly, or nearly one-third of the whole pig-cast of England, Scotland, and Wales. The Cleveland ironstone is cheaply got, but it is lean and highly charged with phosphorus. Coke, on the other hand, is dear, and is likely to become dearer. But by the employment of the most complete mechanical appliances the cost of production has been brought to a very low figure. Had the Middlesboro' ironmasters access to the vast quantities of slack from the Durham and Tyneside pits, they would soon turn out a cheap coke by washing, but there would still be the long carriage by rail. The ironstone is calcined in kilns, but as it is not of the carbonaceous variety—that known as "black-band"—there is no opportunity of effecting the saving which, with that variety, is obtained by coking in close kilns, upon Mr. Aitken's plan, so successfully employed near Falkirk. Even 22 cwt. of the best coke to a ton of pigs seems a large quantity when the heat really absorbed in decomposition, liquefaction, and in raising the temperature of the air is considered. A good cupola in regular work will melt, of some kinds of iron, as much as sixteen times the weight of coke used. Yet cupolas vary greatly, and some, from various sources of loss, will not do half as well as this. And blast furnaces vary greatly also, some using, with the same materials, one-half more fuel than others. Yet it is difficult to see the way to any decided improvement in blast furnaces from which the gas passes off at a temperature hardly above 500 degrees, all the gas being saved and burned under the boilers and in the heating stoves so as to require no other fuel whatever.

The Cleveland forgemasters know how to make a good soft iron, hardly cold short, from their highly-phosphuretted pigs, which, in the ordinary course of things would work into cold short bars. The whole secret, if it be a secret, is in a liberal fettling with rich magnetic oxide of iron, of which large quantities are now purposely imported from Sweden. Mr. Gjers has made some very interesting analyses of the cinder, which was highly charged with phosphoric acid, while the puddled bar was of good, mild quality.

Puddling costs dearly in Cleveland. It is not long since it was 10s. 6d. per ton, but it is perhaps somewhat less now. It seems to be settled that none of the "mechanical puddlers" will ever answer, although Mr. Tooth managed to make some very fair blooms, eight years ago, in his revolving puddling churn. But why, after Mr. Bessemer's patent expires in February next, cannot it be adapted to some extent to puddling, so as to drive off not only the silicon, but a good portion of the carbon by air alone, leaving the puddler half an hour's work or less to be done by hand. A great deal was said, some year or two ago, about the so-called "Richardson process," which was merely injecting air under the surface of the iron in a puddling furnace by means of a tubular rabble. The injection of air in such a manner must have been very ineffective for two or three reasons, and although the treatment could not possibly do harm, it is difficult to see how it could, by being continued for but a few minutes, do any considerable good. Yet much was claimed for it at the time, although nothing is heard of it now. But why should not some modification of the Bessemer converter, on a small scale, and arranged to work into, say, half a dozen or more puddling furnaces, be arranged to bring the iron to the point where only the puddler could finish it? In this case, too, all the iron would be melted in a cupola, which would be cheaper than melting it in the puddling furnace. A large saving of labor and a considerable saving of coal might, it would seem, be thus affected. At any rate, the experiment should be carefully tried.

It would be interesting to know whether the so-called "Radcliffe process," of knocking five or six ordinary blooms into one before shingling, is still being practiced with success. It seems extraordinary that such a "process" should be the subject of a patent, although it may be more extraordinary that any forge master should adopt a "process" so likely to shut in cinder with the iron. The published tests of the iron made by this "process" showed an elongation, in breaking, of but about 5 per cent, which is very little, and indicates harshness and brittleness. By mistaking a column of figures in Mr. Kirkaldy's report, the "Engineer" reported the elongation as 30 per cent.

It would be interesting also to know whether Mr. Bramwell's suggestion, that all bar iron should be rolled in a hoop, can be successfully carried out. There are difficulties in the way of bringing together the two ends of a pile and welding them preparatory to hanging the ring upon an overhung roll, and the necessity for some means of shifting the roll into and out of the outer housing would create an additional difficulty. But, supposing all this once done, and that the hoop could be successively shifted from one grove to another, the bar or hoop would be rolled out with a continuous motion, without, "passing," and without any crop ends. It would be better afterwards to find the weld and cut the hoop there, when it would drop out a straight, clean cut bar.—*Engineering.*

MANUFACTURE OF NAIL-PLATES.—Hitherto much trouble has been experienced in finishing the wrought-iron plates from which cut-nails are made, the trouble arising from the adhesion of "scales" to the finishing rolls. This, by destroying the uniformity of the surfaces of the rolls, caused them to work unevenly and imperfectly, and consequently impaired the smoothness of the plates. A Pennsylvanian inventor has recently invented and put in operation a simple contrivance by which the rolls are automatically kept clean, thereby preventing all hindrance to their perfect operation and insuring the uniform smoothness of the plates. It consists in small friction-rollers so applied in relation with the rolls as to sweep the scales therefrom as fast as formed; the rolls being thus kept constantly bright. By this means, not only is avoided all the trouble of cleaning the rolls hitherto necessary, but the nail-plates are made much better. It is probable that the principle of the device will be applied with profit to the rolls of other machinery for shaping iron while hot.—*American Artizan.*

FORTY-TWO TON HAMMER.—In England a huge steam hammer, weighing 1,000 tons, is being made for the Russian Government. The hammer head weighs 42 tons, the anvil block 500 tons, and it is to be used in forging steel guns.

STEEL AT ANY PRICE.—The amiable journalists who, until the advent of "gunpowder steel," condemned all steel, are deriving consolation from the utterances of Sir William Armstrong, at the Newcastle meeting of the Mechanical Engineers. This gunpowder steel, invented by one Heaton, was, however, an exception to everything else. No words and no superficial measurement of type were sufficient to explore its virtues. It is explicable that Sir William has not visited the deserted "shanty" known as Langley Mill, and from the koran to be found there, developed his knowledge of steel. We are told that he was once one of the "steel at any price" party. So far from this, he has been a most uncompromising enemy of steel in all forms. He stood out, for a long time, and in spite of every recognizable fact, against steel inner tubes for his guns, without which they might almost as well have been constructed of leather. Indeed, there is no such thing now as an "Armstrong gun." The gun is Fraser's and Fraser's only, and he has not yet received the half of what he deserves for kicking aside the Armstrong delusion. Just as engineers complete their education they learn the value of steel, and it is merely a pity that the tergiversating journalists of whom we speak are not yet out of the woods in their wild goose search after evidences of its value.—*Engineering.*

THE PITTSBURGH STEEL WORKS.—The "Black Diamond" Steel Works of Park, Brothers & Co., are the largest in the city, covering five acres, and comprising a steel forge, rolling mill, converting building, melting houses, etc. Here are 17 steam hammers, 5 helve hammers, 7 steam engines, 4 trains of rod and bar rolls. The capacity of the works is 20 tons of cast steel and 10 of common steel, daily, the number of men employed, 240. This concern manufactures cast steel boiler plate for locomotive engines, tool steel, machinery steel, burglar proof safes steel, plough, and other agricultural steel. The buildings and machinery of the establishments are all first-class, and kept in the nicest possible order. This is a sample of the very best class of establishments in Pittsburgh.

The establishment of Messrs. Hussey, Wells & Co., one of the largest steel works in the city, has a capital of $1,000,000, runs 144 furnaces, and makes about 30 tons of steel per day. They employ about 200 men, and sell as fast as they can manufacture, which is the best point that can be made with regard to the steel-workers of Pittsburgh.—*Exchange.*

STEEL-HEADED RAILS.—Steel-headed rails are made at the Trenton (N. J.) Rolling Mills by the following process: The steel which is to form the head of the rail is first wedded to a quite thin piece of iron. The combined bar is then beaten and rolled down until the iron is very thin and the steel reduced to about half its former bulk. After this operation is completed, the whole quantity of iron requisite to complete the bulk of the rail is added to the bottom of the combined bar, and welded to the thin layer of iron. This process, it is asserted, doubles the strength of the weld between the iron and the steel, always a difficult operation to perform. The old process consists in welding the relative thickness of iron and steel at one operation, but the new method is reported to furnish better rails.—*U. S. Railroad and Mining Register.*

REDUCING ALUMINIUM FROM ITS ORES.—Mr. A. L. Fleury, of Boston, U. S., mixes pure alumina with gas tar, resin, petroleum, or some such substance, making it into a stiff paste, which is divided into pellets, which are dried in an oven, then placed in a strong retort or tube, which is lined with a coating of plumbago. They are then exposed to a cherry-red heat. The retort must be sufficiently strong to stand a pressure of from 25 to 30 lbs. on the square in., and be so arranged that, by means of a safety valve or tube, the necessary amount of some carburetted hydrogen gas can be introduced into the retort among the heated mixture, and the pressure of from 20 to 30 lbs. on the square in. be maintained. The gas alluded to is forced into the retort by means of a force pump. By this process the alumina is reduced and the aluminium remains as a spongy mass, mixed with carbon. This mixture is re-melted with metallic zinc, and when the aluminium has collected in a metallic state, the zinc is driven off by heat. The reduction is due to the carburetted hydrogen gas under pressure. The time required for reducing one hundred pounds of alumina earth, cryolite, or other compound of alumina, should not be more than four hours; when the gas can be applied in a previously heated as well as strongly compressed state, the reduction takes place in a still shorter period.—*Chemical News.*

RUSSIAN RAILS.—A great festival has lately been held at the Poutilof rail factory (St. Petersburg) on the occasion of the completion of 2,000,000 pounds (about 800,000 cwt.) of rails. The rise of this factory is mainly owing to the privileges granted by the Russian Government to companies purchasing their railway material in Russia, and to large orders for the governmental lines. Hitherto it might be reckoned that a considerable part of investments of English capitalists in Russian railway shares might come back in the shape of payment for rails and rolling stock. Now we see that, as regards rails, this hope must be given up; and the same thing would probably have taken place in respect of carriages, had not the new Struve's extensive carriage factory (near Moscow) been recently burnt down. Of locomotives and carriages we may further observe that Russian companies have always preferred the cheaper French and German supplies. The Poutilof rails are stated by Russian engineers to be heavier, and nearly twice as dear as the foreign, but more durable.—*The Engineer.*

BESSEMER'S LATEST PATENT.—Henry Bessemer, whose name has been long identified with improvements in the manufacture of iron, has recently taken out a patent in England on a new process, the object of which is to secure a more rapid and less expensive mode of fusing malleable iron and steel of different kinds, and to obtain cast-steel and homogeneous malleable iron therefrom. In order to accomplish this, the inventor avails himself of the property of gaseous fluids to rise in temperature in proportion as they are compressed, and he constructs furnaces of sufficient strength to withstand an internal pressure equal to two or more atmospheres, and retains in such furnaces the products of combustion under such an excess of pressure over that of the external air as will produce the high temperature necessary for rapidly fusing malleable iron and steel of any kind or quality.

RAILWAY NOTES.

Trial of a New Kind of Railway in France. —A commission was appointed to study and report upon a system of railway of which a specimen had been laid down by Mr. Geoffroy, of Rouanne, by the side of the road from Poilly to Charlieu, in the Loire. The principle of this railway, which is intended for local lines, is that the rails are laid on the natural profile of the ground, with the addition of a central rail, upon which work horizontal wheels wherever the curves or gradients are at all sharp—in fact a modification of Mr. Fell's arrangement. The report of the commission is not published, but the following are the conclusions of the reporting engineer: (1.) The system of railways presented by Mr. Geoffroy allows of trains being worked with perfect security on inclines of 0.06. (2.) The arrangement of the railway in those parts where the central rail is introduced seems to resolve the problem as simply and economically as possible. (3.) The breaking off of the central rail in those parts where the incline does not exceed 0.025 causes no inconvenience, adhesion of the vertical wheels being then sufficient; and the horizontal wheels take on and leave the central rail without any shock that can do injury to the machinery. (4.) The action of the brakes of the engine is sufficient to stop a train of twenty-two tons within 80 feet on the inclines of the experimental line. (5.) The engine and carriages pass without difficulty, and without the aid of the central rail, at the rate of twelve or thirteen miles round curves of 260 feet radius. (6.) The passage of the train by the side of the ordinary road did not appear to frighten horses very much; and in any case this inconvenience cannot be very great, on account of the ease with which the engine can be stopped. The effect will also be greatly diminished by the erection of a barrier that must be placed between the railway and the high road." We are sorry to say that the opinion contained in the last paragraph is entirely opposed to that of the engineers and others of Paris and Nantes with respect to the road locomotives and steam rollers, and the latter are not now allowed to be used in the day time, except the street be blocked, on account of the accidents that happened. Still, if costly works can be avoided by the use of a central rail, we may have local railways at a comparatively small expense elsewhere than by the side of high roads, and there is no reason whatever, except the objection of level crossings, why such simple railways should not be adopted. It is the opinion of the commission that there would be a saving of expense in the case of such a railway as compared with ordinary lines of 40 per cent, and that therefore it would be well to adopt the arrangement where the difficulties of the ground would render the construction of an ordinary railway too costly. —*The Engineer.*

The Patent Shaft and Axle Co.'s Works and Products.—This company, says the correspondent of "The Engineer," employ at their two establishments—the Brunswick and the Old Park Works—from 4,000 to 5,000 hands, and that the department I visited occupies 400 workpeople, and turns out weekly over 300 pairs of wheels. My attention was first directed to the manufacture of some solid wrought-iron wheels with Kirtley's spokes fitted with best "double star" puddled steel tires, or tires of solid cast-steel, secured either with Mansell's retaining rings or ordinary bolt and rivet fastenings. Kirtley's spokes are rolled from B B iron in ordinary rolling mills, they are then bent into a triangular shape, so that when eight are placed together they form a complete circle, technically called a "skeleton." The machine in which they are shaped is called a spoke-bending machine. This apparatus has a bed similar to a planing machine, the "saddle" of which is worked to and fro by a cranked motion. The saddle has fixed upon it a center block, and two side blocks or arms. The center block, which forms the crown of the spoke, is moved horizontally by eccentric motion. The side blocks are then simultaneously brought together by a single movement of the machine, embracing the sides or legs of the spoke. After being thus shaped, another movement lifts up the spoke from the die, when it is ready for bossing; that is, the spokes, arranged in a circle or skeleton, are placed on a smith's fire, and the center part is heated to a welding heat, and a large washer formed by a steam hammer, also heated, is welded on to the center of the spokes by ordinary smiths' sledges. The spokes being sloped at the corners of the crown, leave when put together interstices in the shape of the letter V, which are filled up by what are called "V-pieces. The wheel is then ready to receive the tire. The accuracy of the former is, however, first secured either by ordinary lathe-turning, or perhaps (more frequently) by an ingenious apparatus expressively called a "squeezing machine." This machine consists of a circular bed-plate, on which is worked eight slides, which are worked simultaneously to one center, forming a perfect circle. The machine is capable of exercising a pressure of 1,500 tons after making due allowance for all friction. The tires, which are rolled, bent and welded, are also tested in what is called a "blocking machine," an operation which fully proves the soundness of the weld. The tire being expanded by heat is next shrunk on to the skeleton by immersion in cold water, and the wheel is then ready for the finishing touches, such as boring and grooving, to receive the key of the axle. The wheel and the axle are joined together by pressure under gauge by hydraulic power, being further secured by steel keys. The wheels in pairs are turned in wheel lathes to accurate dimensions, and to road gauge, after which they are dressed off and painted. The wheels vary in size from 18 in. diameter, for lorries, to 6 ft. diameter for engines.

American Locomotive Repairs.—From a number of reports of some of the leading American lines of railway, we have compiled, says "Engineering," the following statement of the average annual mileage of their engines, and the cost per mile for repairs. As a general rule, only train miles are reckoned by American railway managers, although in some of the following cases engine miles are reckoned in dividing for the cost of repairs per mile.

The cost of repairs, given in pence per mile, is in a depreciated currency, the cost in silver being about three-fourths that in paper. Allowance must, of course, also be made for the very high price of labor, and all materials, except wood, in the States.

The Reading, and the Baltimore and Ohio Railroads are very largely engaged in the coal traffic, the latter line having 239 goods engines out of a total of 290 of all kinds.

NAME OF LINE.	Year.	Number of Engines.	Total Mileage.	Average Mileage for each Engine.	Cost of Repairs in *Pence* per Mile.

PERILS OF INDIAN RAILWAY TRAVELING.—A late number of the "Cornhill," gives the following interesting facts :—The only accidents peculiar to India are those which are the result of floods, cyclones, and such disturbances of the elements. In 1864, the lower part of Bengal was visited by a tremendous hurricane, but although sheds were leveled to the ground, roofs were torn away, and part of a train, including the engine, was blown over, no lives were lost. On this occasion damage to the extent of £50,000 was done to railway property. On another occasion, on the Bombay side, the results were even more disastrous. A viaduct on the Great Indian Peninsula Railway was carried away by the violence of a flood, and a night train following soon after ran into the vortex, taking with it a number of native passengers, fourteen of whom were killed. The bridge over the Nerbudda River, on the line between Bombay and Baroda, has more than once suffered injury from the violence of the torrent. In Scinde, on one occasion, a whole village on the banks of a nullah was carried away, and brought down a railway bridge in its ruin. Wild animals have also occasionally been the cause of accidents. The other day an elephant charged a train and was killed, but such was the resistance which he offered that the engine-driver was thrown off and injured. A buffalo has also been known to throw a train off the line by getting in its way. In spite, however, of these special causes, railway traveling is as safe in India as in England. Last year the number of fatal accidents was one and a half per million. There are perhaps more frequent cases of death from natural causes in Indian Railway trains than elsewhere, and the ominous heading "found dead" may be seen on the returns of casualties. The fact appears to be that many natives commence a journey *in extremis*, in the hope of reaching some sanctified spot where to die, and the vital spark expires before the poor creature can reach his destination.

FAST RUNNING.—The speed of the New York and Chicago Express, over the New York Central Railroad, has been as high as 51.7 miles per hour for 81 miles, between Syracuse and Rochester.

*Equivalent average for whole year.

PEAT FOR LOCOMOTIVE FUEL.—The State Line Bavarian Railway has been worked with turf since 1847, or for above 20 years, rather from necessity than choice. The peat is got from the bogs of Haspelmoos. The method of its preparation is that of M. Exeter, whose statement is that he can produce 10,000 cubic meters of prepared turf per annum at a cost of 2.80 francs per meter. The turf, as dug or dredged, appears loaded with much admixed earthy matter; from this it is separated by grinding up, large dilution with water, and decantation of the water bearing the light peat particles still in suspension from the heavier earthy matter which has deposited. This is let to dry in layers exposed to the air like "hand turf," and then compressed in molds by power. From other sources of information on the subject of artificially prepared peat, we conclude that these results admit of being contested. As a locomotive fuel, turf, at the best, is a bad and troublesome one; it gives much smoke and sparks, leaves an evil smell after it, experienced in the train, and is so bulky as often to need supplementary wagons to feed the tender on a long run. There is also great waste by the broken particles passing through the fire-bars.

As to comparative heating powers (not theoretic, but taking into account all these circumstances), the result of nine years' working on the Bavarian State Line indicate that 100 cubic feet or 2.486 cubic meters of the prepared turf of average quality and dryness, are equivalent to 312.5 kilograms of coke, or to 3.135 cubic meters of white firewood, *i. e.*, of wood principally of birch, beech and alder. Thus during this interval of working, the cost of firing with turf was about half that of coke (*in Bavaria*), and two-thirds that of wood. But taking everything into account, as derived from the accounts of the line for 1861-62, it may be shown that even this is too favorable, for that the fuel account per kilometer per engine stands thus:—

	Fired with Coal.	Fired with Peat.
Passenger Engines.	0 166f.	0.172f.
Luggage Engines..	0.249f.	0.207f.

It is thus, though rather cheaper than coal for slow traffic, a trifle dearer than coal for fast, and that even in Bavaria, where coal was then exceptionally dear.—*Practical Mechanics' Journal.*

RAILWAY IMPROVEMENT IN NEW YORK CITY.—The Legislature of the State of New York, at its last session, authorized the construction of a railway station on the Fourth avenue, to be used jointly by all trains arriving in this city from the north.—This station will extend from Forty-second to Forty-fifth street, closing Forty-third and Forty-fourth streets, and will occupy an area of about 800 feet in length by 300 feet in width, taking in for this purpose 150 feet on either side of the avenue. The Hudson river road is to be connected with the Harlem and New Haven track, and all the trains of these three roads are to be brought under one roof. The estimated cost of this improvement will amount to $1,000,000, and it is stated that the permanent way of these lines are to be so combined as to permit the freight carried over them to be all delivered at the large depot now occupying what used to be St. John's Park. The advantages which these arrangements will afford to travelers and the commercial community over the present disjointed state of city and country intercommunication, are apparent. —*Scientific American.*

Steel Rails.—Probably nothing is better established in railway practice than the superior economy of steel tyres, as compared with iron, even at twice the original cost per hundred weight. The wear of rails is less rapid than that of tyres, except where the traffic is incessant and enormous. Hence, probably, arises the nice calculation—never applied in the case of tyres—of interest and compound interest, as accruing upon iron and steel rails respectively.

It is now being industriously represented that the royalty on Bessemer steel rails is £2 per ton, and that this royalty will cease, with the expiry of the patent, in February next. The royalty is, and has all along been, £1 per ton only, and of this but 17s. 6d. will cease to be levied in February next.—Steel rails have hitherto been put down mainly on those portions of railways on which the traffic was unusually heavy, and as these portions have, for the most part, been already laid in steel, the necessity for the further use of steel may appear less urgent now than it did a few years ago; but it is none the less urgent where iron rails, in exposed situations, must now or soon be renewed. Rails that can be safely permitted to wear another year, ought, of course, upon every consideration of economy, to be left to fulfill their full service; but there are thousands of tons of iron rails, on our great lines of railway, which will have completely worn out this year and which must, therefore, be renewed before winter sets in. And as it is easy to prove that, under heavy traffic, the wearing value of steel, even at £12 per ton, is very much more, after allowing for the difference of cost, than £1 per ton greater than that of iron rails at £6 or £7, it would be anything but economy to put down iron rails again to last two, three or four years, merely to escape a moderate present royalty, and to take advantage of its diminished amount in 1871, '2 or '3. So far as extensive observations go, the wear of steel is from ten to twenty times that of iron, while as for breakages, the fractures of steel rails do not exceed one per cent of those of iron rails. In situations, then, where iron rails are not likely to wear longer than a year or two, it would manifestly be unwise policy to replace them with iron merely to avoid a few shillings extra royalty on steel. This point is, we think, too well understood to require any lengthened argument, and it is not, therefore, to be wondered at, that within so short a time of the expiry of the Bessemer patent, the steel rail mills continue, according to the current trade reports, to be very well employed.—*Engineering*.

The Reading Railway Shops.—This company has the largest shops, foundries, and rolling mills in the city of Reading, and gives employment to over 2,000 men. The company makes its own locomotives, cars, and all other work necessary to equip and keep the road in running order. Two locomotives are made per month, but the demand for engines is so great that a contract has been made for twelve at the Baldwin Locomotive Works in Philadelphia. In the rolling mills sixty tons of rails are made each day, and in the two foundries 12,000,000 lbs. of castings per annum. The brass foundry yields 200,000 pounds of castings per year, and 1,000 tons of wrought iron are also made during the same period. The pay of the workmen in all the shops of the company amounts to about $85,000 per month.—*American Railway Times*.

Fairlie's Steam Carriage.—The "cabbage garden" at Hatcham is likely to become as famous as the race course at Rainhill, only that there is no *race*, so dear to the heart of every Englishman, except a race against time. Mr. Fairlie has a combined engine and carriage, weighing but $13\frac{1}{2}$ tons empty, and capable of seating 66 persons, which is whisked around the Hatcham cabbage garden—upon a villanous permanent way, not exactly a circle, one-ninth of a mile in circumference, and having three quadrants of 50 feet radius. Seeing *is* believing, and we only regret that there is no Act of Parliament to compel every railway director and every railway Mephistopheles (the locomotive superintendent) to go to Hatcham and see. Thirty miles an hour and more has been accomplished, but we considered twenty-five preferable, and we stipulated for this, and no higher, speed when we sat foot upon the engine bogie. With the Field boiler there was no end of steam—160 lbs. per square inch—and the regulator could hardly be touched by the skillful hands of Mr. Clemenson without giving a jump to the whole affair almost enough to send us into centrifugal convulsions. The gentleman who, after first addressing the Institution of Civil Engineers, declared that the "theater" made 60 revolutions per minute during the whole period of his communication, would have been as much astonished at the circular movements of the little edition of a railway train at Hatcham. Round and around, four times round the cabbage garden, up and down gradient, and almost half a mile, was repeatedly done in one minute.

The merits of this system will not long want appreciation. Even the Ramsbottoms, the Armstrongs, the Stirlings, the Beatties, the Kirtleys, the Cudworths, the Cravens, the Johnsons, the Martleys, the Pearsons, the Connors, the Fletchers, must at last give in. The motion is more like sailing than riding, that is, the motion in the carriages. The "centrifugal convulsions" to which we have referred were generated only upon the engine bogie, and in the next carriage, this being the first of a certain number *in futuro*, the engine will be so connected with the carriage as to prevent any jerking or striking, at full speed, a curve of even three-quarters of a chain radius.

It is but just to Messrs. Brown, Marshalls & Co., to mention that the "train"—all in a single carriage—is the model of comfort and neatness. When we first saw the carriage, in the makers' factory at Birmingham, under a low roof, we took the impression that the compartments were cramped in the matter of space. But in the open air of the Hatcham cabbage garden we found, not alone by the sensation of comfort, but still more so by the act of measurement, that the seats were at least as capacious, and that for thick men, as any known near the Metropolis.

The railway company which first secures the exclusive use of Fairlie's steam carriage has dividends as good as declared for its shareholders.—But with one carriage there will be many, and let us hope that all the companies may, by these means, come round to dividend payments at last.—*Engineering*.

The Manchester, N. H., Locomotive Works have been very much enlarged, and six locomotives are turned out monthly. The works employ 400 men.

PACIFIC RAILROAD TIME TABLE.—The following statement of Time and distances is given by the *Western Railroad Gazette:*

	Miles.	Hours.
New York to Chicago, Ill.	911	$36\frac{1}{2}$
Chicago to Omaha, Nebraska	491	$24\frac{1}{2}$
Omaha to Bryan	858	43
Bryan to Ogden, Utah	233	$10\frac{1}{2}$
Ogden to Elko, Nevada, via Central Pacific R. R.	278	$12\frac{1}{2}$
Elko to Sacramento, Cal., via Central Pacific R. R.	465	31
Sacramento to San Francisco, via Western Pacific R. R.	117	$3\frac{1}{2}$
	3,353	$161\frac{1}{2}$

Thus a total distance of 3,353 miles is made, according to the present schedule time, in 6 days and $17\frac{1}{2}$ hours, actual time, by a traveler's watch, from which we deduct $3\frac{1}{2}$ hours difference of time, when going West, leaving the apparent time consumed in making the trip 6 days and 14 hours.

At San Francisco the mails will connect with the various steamship lines running on the Pacific, and may be landed in Honolulu in 9 days from that city, or $15\frac{1}{2}$ days from New York. They can reach Japan in 19 days from San Francisco, or $25\frac{1}{2}$ days from New York, or 33 to 34 days from Great Britain—thus beating the British mails sent via Suez, three to four weeks. The trip between Yokohama, Japan, and either Hong Kong or Shanghai, is readily accomplished by the Pacific Mail steamships in from five to six days, which, added to the time in reaching Japan, will give the through time necessary to reach either of the above named ports of China.

The mails for Australia, it is thought, will hereafter go via San Francisco. as the Australian and New Zealand Steamship Company intend transferring the terminus of their line, which has been running from Sydney to Panama, so as hereafter to run from Australia to Taluti, thence to Honolulu, and thence to San Francisco, making 28 days schedule time, which will give us monthly mail to Australia in 34 or 35 days through time.

STEEL-CAPPED RAILS.—A paragraph has been going the round of the press, stating that the Hartford and New Haven Railway Company had ceased laying down steel rails, for the reason of their "stiff, unyielding character." As rail stiffness is what our engineers have long been striving for, the reason given was rather odd, to say the least. We have never found a rail too stiff for a thirty-two ton engine, going at speed, and probably no one else has. The section of rail should always be heavy or stiff enough to prevent any deflection when the driving-wheel passes between the sleepers; if not, the wheels are constantly running up and down short inclines, producing that unsteadiness of movement and pounding that is so destructive to both rails and wheels. The rail is nothing but a girder, and the more strong and stiff it is, the safer and better it is for every purpose Any elasticity of the track should be applied in the superstructure below the rail. We understand that the Hartford Company has ceased laying down steel-capped rails for the reason that the officers desire to test their utility before further expense is incurred. They have some fifteen hundred tons in the track, and at present it is doing well. The principal objection urged against the iron rail covered with steel is, that the steel will flake off by wear. The makers, on the other hand, claim that their system of uniting the two is complete, and that the steel will adhere until worn off. The durability of steel-capped rails is a matter which requires more experience to determine, though a lot of Prussian make (Funcke & Elbers) laid on the Boston and Providence road are showing fine results. These rails are not made of Bessemer but of puddled steel, and the method of piling in manufacture differs from common practice, it being vertical instead of horizontal, so that the weld being perfect, any defect or want of homogeneousness in the material will show itself in the head by a depression, instead of flaking off or laminating is seen in many makes of iron rails. The Prussian rail can be cut and notched in the flanges without any fear of a succeeding fracture at the point cut, and there is equal security against fracture at the bolt holes for the fish-plates. We must confess to some doubt as to the wearing qualities of an iron rail with a Bessemer metal cap shrunk on around the head, the difficulty being in getting a good weld; but we understand that it has been done with promise of good results. Our railway companies are making money enough to allow them to make a fair trial of all the new devices and we trust that they will do so, so far as they can without impairing the safe character of travel.—*Railway Times.*

THE SWISS ALPINE RAILWAY.—Besides the great engineering triumphs of the nineteenth century—the Suez Canal and the Mont Cenis—another work of no less magnitude is now claiming universal attention, namely, the Mont Saint Gotthard Railway. After the Prussian and Italian ambassadors notified lately to the Swiss Confederation the material support of their respective governments towards that undertaking, a conference was assembled at Lucerne for the purpose of taking the initiative in the matter, and to arrange a financial programme. Dr. Alfred Escher, the eminent Swiss statesman and railway director, reported that of the necessary capital—6,500,000*l.* sterling—2,500,000*l.* will be found in Italy, 2,000,000*l.* in Germany, and 2,000,000*l.* in Switzerland, these sums being composed of 3,600,000*l.* subventions, 1,000,000*l.* in obligations, and the rest in shares, the greater portion of which has already been subscribed for in Switzerland.

In the construction of the Saint Gotthard line the project, adopted by the Italian commission, will be principally adhered to. This project includes a perfectly straight and nearly level tunnel of $9\frac{1}{4}$ miles in length, the northern tunnel mouth at Goeschenen will be 1,100 meters, the southern at Airolo 1,130 meters, and the tunnel summit 1,137 meters above sea level; and this tunnel the contractor of the Mont Cenis tunnel has offered to execute in eight to nine years, including steel rails, for the sum of 2,480,000*l.*

Another project, proposing a surface line, rising at the rate of 1 in 20, to 1,800 meters' height, has been condemned, as not affording that expeditious, safe, and economical working as the lower line with long tunnel. This consideration has carried all the more weight with it, as the future Swiss Alpine Railway will have to compete with the Mont Cenis, Brenner, and the French Mediterranean lines. It has been stated that on this latter line, having no steeper gradients than 1 in 200, the working expenses of one ton net are only one farthing per kilometer, while the carriage of one ton net on gradients of 1 in 20 would cost four times as much, or one penny per kilometer; and, moreover, the surface line being double the length of the lower line, the working expenses would accordingly be in the ratio of 1 in 8. The lines connecting the Saint Gotthard tunnel with the Swiss and Italian railway system will still, however, present some heavy gradients and sharp curves.

We understand the attention of the Saint Gotthard Commission has been directed to Mr. Fairlie's double-bogie engines, and that gentleman's plans have been regarded with much favor and interest.—*Engineering.*

Electric Lights on Railways. — According to the American journals a novelty in railway management is to be introduced by the Erie Company, who propose to illuminate the whole line of that road at night by electric lights at the ferries, in the tunnels, on all dangerous curves, and on every engine. Mr. E. C. Morse, who has charge of the matter, states that he has made several important improvements, among others a plan for preserving the carbon points from wasting away and keeping them for months in good condition, a self-sustaining battery, and an invention by which the turning of the wheels of the engine shall collect electricity for use in illumination. There will be a light at each end of the ferry, which it is believed will make a collision practically impossible on the darkest and foggiest night. Even with the diminution of light caused by the jarring of the locomotive, it is estimated that the head-lights will show the track to the engineer on a straight line for three miles. More welcome, however, than any announcement of material improvements would be a notification in the cause of public morality that the managers of this line could be brought to a condition of responsibility for the pecuniary claims of the shareholders.—*Engineering.*

Speed and Power of Locomotives.—The *speed* of an engine depends on the rapidity with which its boiler can generate steam. One cylinder full is required for each stroke of each piston. Each double stroke corresponds to one revolution of the driving wheels and to the propulsion of the engine through a space equal to their circumference. Wheels seven feet in diameter pass over twenty-two feet in each complete revolution. To produce a speed of seventy-five miles an hour, they must revolve exactly five times in a second; and to effect this revolution, each piston must make double that number of strokes in that time, and consume ten cylinderfuls of steam. The *power* of an engine in drawing loads depends on the pressure of the steam, which is usually about 120 pounds on the square in. It is also limited by the adhesion between the track and the driving wheels, which is proportional to the weight pressing on the latter; so that instead of the weight being an obstacle, it is one of the principal elements of power. The tractive power of an engine of 40 tons, with 32 resting on the drivers would be about 4 tons —*American Artisan.*

New Railways in the United States.—It is believed that at least 5,000 miles of new railroad will have been opened in the United States in the course of the year 1869. Already the returns show a mile to every 876 of the population.

The Reading Railway Co. are making very superior iron rails at their own mill by simply putting plenty of work on the iron.

NEW BOOKS.

A Practical Treatise on Modern Screw Propulsion. By N. P. Burgh, Engineer. London: E. & F. N. Spon, Charing Cross. 1869. New York: D. Van Nostrand, 23 Murray street.

Mr. Burgh's important treatise on the screw propeller, the publication of which in numbers was commenced nearly two years ago, now lies before us as a handsome volume. We have already referred at some length to the first chapters of the book, and it is therefore unnecessary now to consider their contents again. They consist, it will be remembered, essentially of an opening chapter by Mr. Burgh, and a historical introduction from the pen of Mr. G. B. Rennie, M.I.C.E., which is contained in seventeen pages. We are not aware of the existence of any historical notice of the screw propeller at once so short and so good, and having said this much we fancy we have said all that is requisite to indicate the character of the chapter. Starting from this point we find next a treatise or chapter—which the reader will—on the geometry of screw propellers in general, written by Mr. Burgh, and this is followed up by a history of the Griffith's propeller, written by Mr. Griffiths himself; a chapter on its geometry by Mr. Burgh, and one on the geometry of the paddle wheel by Mr. Barclay. Here we must stop for the moment, as we do not intend to publish a list of all the chapters in the book; the more important we shall refer to in their proper order as we go on. The distinguishing feature of the volume is, that a large portion of it has been written by men of enormous practical experience. Besides the chapter by Mr. Rennie already referred to, we find here distinct, compact, neatly written treatises, based on special points of practice, from the pens of such men as Mr. Griffiths, Mr. John Penn, Messrs. Maudslay and Field, Messrs. Dudgeon, Captain Symonds, Mr. Langdon, etc., etc. The book, as a whole, therefore, constitutes an encyclopædia of the screw propeller, possessing the immense advantage over all other works on the same subject that it is written not by one man, but by several who are specially qualified to express the most valuable opinions, and to supply the most valuable information which is attainable. This fact alone would suffice to establish the character of the volume as the best work in existence on the screw propeller; but, in addition to this, a single glance at the volume will show that it contains a set of engravings which are absolutely unique. They represent to a fair scale, not the screw propeller of the past, not the screw propeller as it exists in patent office specifications, not as it lies in the brains of inventors, but the screw propeller, and every detail connected with it, as it exists in the naval and mercantile marine of Great Britain, and as it has come from the hands of the very best mechanical engineers in the whole world. It would be quite possible to take these engravings into any drawing office, and to prepare from them a set of drawings by the aid of which the designs "depicted"—to use a favorite word of Mr. Burgh's—could be carried out in practice. This is the highest praise which any engraving can receive, and, knowing this, we award it cheerfully to Mr. Burgh's lithographs.—*The Engineer.*

The True Basis for the Construction of Heavy Artillery. By Lynall Thomas. London: F. Taylor and Francis, Red Lion-court, Fleet street, 1869.

A Course of Six Lectures on the Chemical Changes of Carbon. By William Odling, M. B., F. R. S., Fullerian Professor of Chemistry, Royal Institution. Delivered before a Juvenile Auditory at the Royal Institution, Christmas, 1868–'9. With Notes by Wm. Crookes, F.R.S. London: Longmans, 1869. For sale by Van Nostraud's.

Dr. Odling's Christmas Course of Lectures for Juveniles, at the Royal Institution, were no doubt attended by some of our readers, who, though childhood's time is gone with them, consented under the circumstauces to the imputation of being still only big boys. To these and to all others who were present at the delivery of the lectures, the permanent record of them by Mr. Crookes will, we are sure, be very welcome as a *souvenir* of some happily spent hours. To listen to a lecture in which the nature of some group of natural phenomena is set forth in a form clear and distinct to the entirely uninitiated by a master hand, has always been to us a keen pleasure. Dr. Odling possesses in a special manner the power of comprehensive exposition, which, united with enviable qualities of voice and manner, renders his teaching unusually attractive.

The title of this course of lectures—*The Chemical Changes of Carbon*—only imperfectly indicates their subject-matter. For the benefit of those—necessarily the great majority—of our readers who did not hear the lectures, we will briefly enumerate the principal matters touched upon the method of the course. Concerning the method, it is that of passing from one fact to some other to which it naturally leads, making the selection according to the object in view—that is to say, it is the common method of passing from the known to the unknown. This method has been, however, more extensively followed in these lectures than is usual. Mr. Crookes in his preface to the lectures says, and we quite agree with him:

"A remarkable feature in these lectures is the fact that every term made use of is defined as it occurs, and the oral definition is supplemented by a clear and decisive experimental illustration."

Of carbon itself, its three forms are described—namely, charcoal, graphite, and diamond, while of its compounds the three following are selected—carbonic gas (carbonic acid), carbonous oxide (carbonic oxide) and carbonic disulphide (sulphide of carbon), to which we might add marble from the considerable incidental notice it receives. The carboneted hydrogens are not studied. The physical and chemical properties of the atmosphere are pretty largely treated of, and the phenomena of combustion, oxidation and reduction, and of the diffusion of gases. The solubility of gases in liquids, the conversion of gases into liquids, and the reconversion of the latter into gases with the attendant phenomenon of the production of great cold are also fully illustrated. So, too, is the remarkable power of charcoal of absorbing gaseous bodies and withdrawing substances from solution.

Mr. Crookes has added an appendix of notes which is very useful. It might seem, at first, that a studiedly simple exposition ought to need no explanations, but it must be remembered that facts may be adduced to illustrate a point, and do so without ambiguity, at the same time that many particulars concerning them may receive no attention. But these facts after they have served the purpose for which they were brought forward, may still excite inquiry in the mind as to other things about them. Mr. Crookes' notes meet such a curiosity. To both the author and the editor of these lectures the friends of scientific education must feel themselves indebted.—*Scientific Opinion.*

The Soldier's Pocket-Book for Field Service. By Colonel G. J. Wolseley, Deputy Quartermaster General in Canada. For sale by Van Nostrand.

When, from time to time, we read of the publication of some military work of instruction, our first impulse is to look out in the Army List for a detail of the author's services, as we have a natural repugnance to wading through volumes of theories by men without war experience, who can only tell us what they think active service ought to be. Strange to say, almost all our military works are by such men. Many of their books are clever, and calculated to turn attention to military subjects, but all lack the clear ring of the practical about every page, bearing upon it unmistakable evidence that what it contains is either a personal theory or an extract from some foreign author. Whatever may be the shortcomings of the little handbook whose title heads this article, it is, at least, by one who is entitled to instruct us in war. Indeed, we know of no officer whose varied experience of active service and upon the staff fits him so well to be the author of such a work. It is intended, he tells us in his preface, for all three arms and for men of every rank; that the information it contains is the result of his own personal experience, and that it is, therefore, of an essentially practical nature. Throughout its pages there are extracts from our military regulations. It is a curious circumstance that there is but little in them which is applicable to war. If a man, from some unknown country, were to pore through them, it is possible he might imagine that to "march past in slow time" was *the* object for which our Army existed. War is, doubtles, alluded to occasionally, but only as a possible contingency. The consequence is, that when officers—even those of many years' standing—find themselves for the first time standing in front of an enemy, they are at a loss how to act. When such men are in command of regiments, unless they are of great common sense and sound judgment, the service must suffer from their endeavors to carry out in the field the routine of barrack life, to which noble (?) subject so much space is devoted in all our official regulations. Colonel Wolseley's handbook will be to all such men a *vade mecum* of great value.—*Army & Navy Gazette.*

Official Railway Manual of the Railroads of North America for 1869–'70; showing their Financial Condition, Mileage, Cost, Earnings, Expenses and Organizations; together with a List of the Railroads of the World. Compiled from Returns furnished by the Companies. By James H. Lyles, of Lindsay. Walton & Co., 56 and 58 John street, New York.

This is a complete directory in everything relating to the Railways of the United States. It contains, besides a full statement of the finances and engineering particulars of each road, full lists of the directors and all officers, statements of the rolling stock and locations of the shops, information as to the election of directors, and a great deal of miscellaneous information of value to persons in any way interested in railway matters.—*American Artizan.*

MÉMOIRE SUR LA COMPOSITION CHIMIQUE DES MONNERIES NÉERLANDAISES ET SUR LA VOLATILISATION DE L'ARGENT. Par A. D. VAN RIEMSDIJK, Docteur des Sciences. Pp. 38.

This is an abstract, reprinted and separately published, from the "Archives Nécrlandaises," vol. iii, 1868. The larger work was written and published in Dutch early last year. It treats on a subject which can only satisfactorily be experimentally studied in a well-arranged Mint; and Dr. Van Riemsdijk, having that opportunity at Utrecht Mint, has thoroughly gone into matters with great zeal and industry. It will be clear, even to a casual observer, that divers chemical changes must of necessity occur to the alloys intended to be converted into coin during the many operations the alloy is submitted to before it leaves the works; it is simply impossible to melt together two metals, and afterwards again anneal the partly rolled out bars, without some chemical change being called into play, The various changes and effects, also, of the blanching and cleaning of the alloys have been studied and experimented upon by the author. He has extended his experiments not only to Netherlands, but also to Belgian, French, Peruvian, Bolivian and Chilian silver coins. Gold coins are not made at the Utrecht Mint as current Netherland coins; hence no experiments were made with gold. The author has also investigated the capability of silver, both pure and alloyed, for absorbing and occluding various gases, especially hydrogen and oxygen gas. On the whole, those who work in silver on the large scale, and are interested in the real composition and constitution of the alloyed metal, will find in this paper many very interesting and useful hints, while assayers will certainly read with pleasure the information contained in these pages.—*Chemical News.*

BIBLIOTHÈQUE DES PROFESSIONS INDUSTRIELLES ET AGRICOLES. Edited by EUGENE LACROIX. Paris: 54, Rue des Saints-Pères.

This latest scientific publication of M. Eugène Lacroix—the indefatigable editor of the *Annales du Génie Civil* and the *Etudes sur l'Exposition*—is calculated to considerably enhance, not only his own already well-earned reputation, but also those of the able contributors by whom he has been assisted. Although the last-mentioned work (*Etudes sur l'Exposition*) is not quite finished, there being one more volume and the index unpublished, M. Lacroix has already published several volumes of a new work, entitled *Bibliothèque des Professions Industrielles et Agricoles*, which appears to embrace a large field of subjects. Thus the *Théorie Mécanique de la Chaleur*, which is translated from the German of Professor Clausius into French by Dr. Folie, is a very elaborate and complete treatise upon this difficult subject, but one which is most important to engineers and all interested in the economy of fuel. The second part of this treatise relates to the relation of the mechanical theory of heat to electricity. The next volume is upon a different subject, being an *Essai sur l'administration des enterprises industrielles et commerciales,* by M. Lincol, and will be found of great assistance to capitalists and managers of commercial enterprises of every description. A chapter entitled "Du rapport entre entrepreneurs et employés," in which the rights and obligations of employers and employed is considered, is well worthy the attentive perusal of both classes there indicated.—*The Artizan.*

PRACTICAL SPECIFICATIONS OF WORKS executed in Architecture, Civil and Mechanical Engineering, Road-making and Sewerage; to which are added a series of useful agreements and reports. By JOHN BLENKARN, C.E., and Architect. Philadelphia: H. C. Baird, 1868. 8 vo. pp. 416.

Projectors of promising and important enterprises are not always wide-awake as to the financial details essential to the beginnings of carrying out. Here lies the wide gap between all the fine plans that are conceived, and their execution. There exists, accordingly, a class of more practical and less presuming engineers, who are sometimes called contractors and sometimes boss laborers, and whose care and specialty is to be clear on all questions of cost, and specification in detail. The present work is intended to assist engineers and architects with examples and methods, chiefly of specifications accompanied by plans, in the acquisition of such all-important practical points in the business of an engineer in full reputation and activity, as could otherwise be acquired only by many years experience.—*Mining and Scientific Press.*

ON MECHANICAL SAWS. From the Transactions of the Society of Mechanical Engineers, 1867. By S. W. WORSSAM, Jr. Illustrated by sixteen large folding plates. Philadelphia: Henry Carey Baird, Industrial Publisher, 406 Walnut street. Price $5.

The saw, there is good reason to believe, is one of the oldest of all the instruments used in the mechanical arts; and it has certainly played a more conspicuous part than any other in the history of civilization, though it is a subject on which little has been written. Mr. Worssam's book treats more particularly on the several kinds of saws driven by steam or other power—reciprocating, rotary and endless band. It discusses the various forms of teeth, with very copious illustrations; gives some valuable information on sharpening and setting, and on gauges, files and saw-sets. It also gives illustrations of saw sharpening machines. The work is a valuable addition to industrial literature.—*American Artizan.*

THE ELEMENTS OF THEORETICAL AND DESCRIPTIVE ASTRONOMY; for the use of Colleges and Academies. By CHARLES J. WHITE, A. M., Assistant Professor of Astronomy and Navigation in the U. S. Naval Academy. Philadelphia: Claxton, Remsen & Haffelfinger, 819 and 821 Market street.

This is a comprehensive though concise manual of the principles of astronomy, adapted to colleges and the higher grades of academies. It contains the latest information on every branch of the subject, including the recent interesting discoveries made by the aid of the spectroscope. We recommend it to those who wish to know the general principles and present state of the science of astronomy.—*American Artizan.*

THE OPERATIONS OF WAR. By Colonel EDWARD BRUCE HAMLEY, C.B. Blackwood. For sale by Van Nostrand, New York.

In closing a long review of this volume, the "Army and Navy Gazette" says: "We feel that Colonel Hamley has done good service by its publication; he has critically considered the revolution that has taken place within so brief a period in the operations of war; has weighed the consequences calmly and deliberately, and has offered his conclusions in a manner calculated to command attention."

THE RUTHVEN HYDRAULIC PROPELLER versus THE SCREW AND PADDLE. London: J. Haddon & Co.

This pamphlet, which the author has been too modest to own, proceeds from the "Ruthven Hydraulic Propeller office," and, as might be expected, is devoted to the task of proving that the Ruthven propeller is the best method of propulsion in existence. In order to accomplish this feat it has to be demonstrated that the Admiralty experiments with the hydraulic-propelled *Waterwitch* and the screw vessels *Viper* and *Vixen* were erroneous. This is done by asserting that in the *Waterwitch*, at the time of the trials there was an enormous leakage of steam, although Mr. Murray could not discover it. Considering the eminence of Mr. Murray in his profession, and also that the engines were one of Mr. Dudgeon's best jobs, it requires a considerable amount of credulity to accept the assertions contained in this pamphlet.—*The Artizan*.

A TREATISE ON ROPE MAKING, AS PRACTICED IN PRIVATE AND PUBLIC ROPE YARDS; with a Description of the Manufacture, Rules, Tables of Weights, etc., adapted to the Trade, Shipping, Mining, Railways, Builders, etc. By ROBERT CHAPMAN, formerly Foreman to Messrs. Huddart & Co., Limehouse, London, and Master Ropemaker of H. M. Dockyard, Deptford. Revised edition. Philadelphia: Henry Carey Baird, 406 Walnut street. 1869. Price $1 50.

Besides containing calculations and other information indispensable to the practical rope-maker who desires to thoroughly understand his business, this little book contains much that should be known in the various trades and professions in which cordage is used.—*American Artizan*.

THE MECHANIC. Vol. 1, No. 1. New York. C. Rogers & Co., 229 Broadway.

This a new weekly containing some dozen pages of matter and many wood cuts. The prospectus says: "That such a publication is required may be seen from the fact that, by the census of 1860, there were not less than 140,433 manufacturing establishments in the country, employing 1,311,246 persons, of whom 1,040,349 were males. Judging from the number of applications for patents there must be from 75,000 to 100,000 active inventors in the country, most of whose improvements are specially adapted to manufacturing processes and products."

THE MILLING JOURNAL AND CORN EXCHANGE REVIEW. New York: J. Q. Nolan & Co., 95 Liberty street. June, 1869.

This monthly journal has been enlarged and improved, and ought to be read with interest, we think, by all men in the department specially appealed to, and by artizans in general.

THE REPORT OF THE STATE ENGINEER OF NEW YORK ON RAILROADS FOR 1868.—We have in previous numbers of this Magazine quoted in full Mr. Sweet's able article on the manufacture and endurance of iron and steel rails and on permanent-way in general. Probably no governmental paper containing so much practical knowledge of the requirements of modern permanent-way, has ever been given to the profession. But this treatise is a very small part of the State report. The particulars of cost, management and working, for all the roads, are given in great detail.

MISCELLANEOUS.

COAL MINE DISASTERS IN THE UNITED STATES.—The more important recent disasters are thus recapitulated in the "New York Times":

In five years, there have been but six accidents worthy of mention, apart from the one which has just occurred; and two of these are of a nature not peculiar to mining. Thus, at Phœnix Colliery, Schuylkill Haven, on the 23d July, 1864, while a car loaded with miners was being drawn up the incline, the chain broke, the car was precipitated downward, and the twenty-one occupants of the car were killed. In July of the following year a flood occasioned by rain imprisoned the men employed in a coal mine at Mahoning, Ohio, from Friday till Wednesday; they were rescued by drilling another shaft. On the 3d April, 1867, an explosion fired the Clover Hill Mine, Pennsylvania, and about seventy miners—all that were at work—perished. In this case there were two shafts, both of which were closed with the view of controlling the fire. In November of the same year Pine Ridge Colliery, near Wilkesbarre, was closed to extinguish fire-damp; when opened, after some days, an explosion took place. At Diamond Mine, Scranton, in March, 1868, twelve men were killed by the breaking of a hoisting chain. The next casualty of which we have any record occurred eleven or twelve days ago in the Pine Ridge Colliery, in the Wilkesbarre neighborhood. An explosion of fire-damp gave rise to the fire at the entrance of the mine, in which thirty men were at work. Their extrication alive would seem, from the published statements, rather the result of Providential incidents than of any help which man was enabled to render.

And now comes the greatest calamity of all—the fire in the Steuben Mine, and the almost certain suffocation of more than two hundred miners. In this instance it is believed that fire was communicated from the ventilating furnace to the woodwork at the bottom of the shaft; the flames rushed upward with frightful velocity, and at the surface reached a mass of wooden buildings, which no effort could save. Burning timbers and rubbish soon filled the shaft, and, as no second outlet had been provided, the fate of all in the mine appears as certain as it is horrible. When at length a passage was obtained, it was only to find the accessible part of the mine filled with poisonous gases.

AVELING & PORTER'S STEAM PLOWS AND STEAM ROAD ROLLERS.—At Beauvais, France, June 30th, Messrs. Aveling & Porter, of Rochester England, and 43 Exchange Place, N. Y., exhibited their Steam Road Roller and their Steam Plow. The Emperor and Empress of the French were present and devoted an hour to the examination of Messrs. Aveling's machinery. The Emperor expressed himself highly gratified with the various machines and presented Messrs. Aveling with a gold medal for their Steam Road Roller, and another gold medal for their steam plowing machinery, which at the special request of the Emperor plowed up a portion of the highway, and without breaking any part of the machinery.

WOODEN GAS PIPES.—A firm in Oshkosh, Wisconsin, has contracted to make 1,000,000 ft. of wooden tubes to lay down in that city for gas pipes. They are made of timber 6 in. square, bored in the same way as pump barrels.

Steaming and Rowing—An Engineering Parallel.—One of the most remarkable features of modern steam navigation is the general substitution of the screw for the paddle. Indeed, the screw steamer has nearly driven its rivals from the stormy Atlantic, where the merits of submerged propellers and heavy spars are most manifest, and is fast chasing them from more pacific waters the world over. The "Persia," which but fourteen years ago was considered the perfection of naval architecture, was last year sold for £15,000, to be changed from paddle to screw. Just as the Cunarders were experimenting with their first screws, the new French line to this country was started with paddle ships. One of them, the "Washington," which formerly steamed ten miles an hour with 96 tons of coal per day, has since been fitted with screws, and now steams 11.8 miles with 83 tons of coal; and the new ships of all Atlantic lines are invariably propelled by screws.

The greater economy of the screw ship with a given speed and load, or her greater speed with the same fuel, are not due entirely to the fact that the efficiency of her propellers as compared with that of paddle-wheels is less impaired by the rolling of the vessel—not entirely to the fact that the screw steamer, by reason of the submersion of her propeller and its indepencence of the rolling of the ship, can carry more canvass and can sail on her beam ends as well as on an even keel, as far as applying the engine power is concerned. Nor does the superiority of the screw ship lie entirely in her greater capacity for stowage, by reason of the greater compactness of her engines, nor yet in the improvement of her machinery for generating, superheating, distributing and condensing steam, since all these may apply equally to the paddle steamer.

One of the notable differences between the new practice and the old, both in ships and locomotives, is the high speed of piston adopted in modern engines. The paddle engine is a great lumbering, heavy machine, moving at the moderate speed suited to the paddle-wheel. The screw engine is compact, light and lively, and it pulls the quick stroke demanded by the screw. A horse power is 33,000 pounds lifted one foot in a minute, or one pound lifted 33,000 feet in a minute. Now the paddle steamer principle carried to excess would illustrate this law by lugging around the 33,000 pound weight, and lifting it a foot, while the screw steamer would be burdened only with the one pound, which it would lift 33,000 feet. The total power is the same, but while in the one instance, a large percentage of it is neutralized in carrying itself—in carrying the cumbrous enginery by which its great force works through a small space—in the other instance, the enginery is small and light, because it has only to transfer a small force through a great space, and speed does not weigh anything.

There are many illustrations of this law in practice. The old style of locomotives with immense driving wheels, big cylinders and ponderous parts, has given place to light-moving parts, small drivers and quick stroke. A small cotton cord running at 60 miles an hour through a machine shop does the work of cumbrous cranes crawling a few feet a minute.

This engineering law and these illustrations establish the correctness of the quick stroke adopted by the Harvard oarsmen as compared with the long, slow, beam-engine stroke of Yale. Speed is an element of power that weighs nothing. If some element that is ponderous is substituted for it, a part of the total power is lost in the machine itself. —*N. York Times.*

Brown's Patent Stop Valve, or Gate.—This is a sliding valve differing materially from, and having many advantages over the wedge valve. It is simpler, stronger, more effective, less liable to leakage, and more easily repaired. Its essential feature is a compound lever brace, or toggle-joint, which acts at the center of the gate, and at nearly a right angle with it. The pressure of the brace is very powerful, and having a center bearing, is distributed equally at every part, forcing the gate firmly to its seat; thus preventing that unequal bearing and consequent leakage, which in wedging valves is incident to imperfect adjustment, uneven wear, &c. The brace, though pressing powerfully, is instantly and freely relieved, for it moves through an inclined groove, and has a rolling motion at each end, thus avoiding all danger of sticking, as in wedging valves. The brace effects great pressure, and consequent tightness, with far less friction and wear than is possible with wedging valves. The gate is held gently to its seat by ribs in the box, so that as it moves, it clears the seat of any foreign substances which might otherwise get between the gate and seat and cause leakage, as in wedging valves; these ribs also relieve the stem from too great strain upon it. The valve is easily repaired, for the gate, brace and stem can readily be removed from the box without disturbing the pipe.

The small sizes, of bronze, are made unusually heavy, to prevent twisting, and of the best steam metal. The iron gates are also very heavy, and of a cylindrical and spherical form, to resist great pressures, and to prevent springing and leakage. It is as cheap as any other sliding valve, notwithstanding its great superiority in principle, construction and action. It is used by many of the largest works in the country, and is conceded by the most eminent engineers and machinists to be one of the best valves known.

Steam Hammers.—Messrs. Morrison & Co., of Newcastle-on-Tyne, some time ago made a very large steam hammer, on their patent principle, for the Aboukoff Steel Works, near St. Petersburg. The piston and piston rod form, of themselves, the hammer, and thus fractures now and then occur. To renew the piston rod, or hammer head, in wrought iron, costs £3,000, or, in puddled steel, £4,000. Messrs. Thwaites & Carbutt, of Bradford, are about to alter this hammer, putting in new standards, with ordinary piston, piston rod, and "tup."

Old and New Coal.—Our attention has been lately drawn to a curious observation which stands, as yet, as a fact without a sufficient reason. In one case, where hard coal is used in large quantities for purposes of me re evaporation, it appears that some which has been kept on hand in open piles for five or six months, is less effective by from 13 to 15 per cent than that freshly mined. A similar result, corresponding even in the percentage of deterioration, appears in another report from a smelting furnace. The deterioration from decrepitation, caused by absorption of water, is of course well known, but does not seem to apply to these cases.—*Jour. Franklin Inst.*

WOODEN AND CONCRETE PAVEMENTS.—Mr. Julius W. Adams, Chief Engineer of the Water and Sewerage Commission, Brooklyn, recently made the following report to the Board, which was adopted :

"The Nicolson pavement is too well known to require comment. It is extending in use in the Western cities, and although from the nature of the material, it cannot be expected to last as long as stone, yet its other acknowledged advantages commend themselves to a large class of our citizens.

The A. Miller pavement possesses, in my opinion, peculiar advantages over the Nicolson, as will be explained more particularly and at length hereafter, and I think the Board will be justified in adopting it, whenever they may have determined to use wooden pavement, as being equal at least to the Nicolson.

The McKenzie pavement has some merit, but it has some of the defects of the Nicolson to a greater degree than the latter, which may prove in practice to counterbalance its other advantages. A practical test is needed before its claims to being an improvement on the first-named pavements can be admitted.

The Williams pavement has an advantage in that it is prepared to be laid on a bed of concrete. It comprises in fact the concrete and wooden pavements, with a consequently increased cost. The merit claimed in the key of bituminous concrete is a fallacy, in my judgment, and is so far an experiment that until tested in practice I could not recommend the adoption of the plan by the Board.

The Miller pavement, with inclined blocks, experience has shown to be inferior to plans with the piles placed vertically, and is probably the least to be commended of any plan submitted to the Board.

Of the concrete pavements I have no evidence that either the Fiske or the Scrimshaw has any advantages, the one over the other. This pavement is extending abroad, but it has the merit in France of being composed of the native asphalt, which is not found in our country; and the imitations of it, composed of tar and gravel, it is known are very inferior to the native material. Laid on the present cobble pavement, properly repaired, it may give good results. The Hoyt pavement is a mere experiment, and possesses no merit that I can perceive over the Fiske or Scrimshaw. Neither of this nor of the remaining plans submitted have I sufficient evidence before me to justify my recommending them to the Board at this time."

DIFFERENTIAL PULLEY BLOCKS.—Messrs. Tangye Brothers, Cornwall Works, Smethwick, produce in large quantities, as a special branch of manufacture, Weston's differential pulley blocks, of which since 1859 not less than 30,000 have been turned out here. These are the only pulley blocks yet made in which the weight is supported without risk of running down while the cord or chain is hanging loosely. The multiplication of power also can be carried to almost any extent with an exceedingly small amount of friction. These blocks, besides their extensive use in all warehouses and manufactories, have found several special applications. While recovering from his illness in 1865, the King of the Belgians was accustomed to ascend from one floor of his palace to another by means of these blocks, a suspended couch being provided, from which his Majesty, with very slight exertion, could raise or lower himself at pleasure. In a note to the inventor, General Garibaldi recommended their use for remounting artillery thrown down on the battle field. The watchman on the lofty fire observatory at Hodges' Distillery, in London, raises himself easily and rapidly to a height of 135 ft. At an *abattoir*, near Brussels, 120 pairs are used in hoisting and hanging the carcasses of the slaughtered beasts. Prince Napoleon in person purchased a pair at the Battersea Agricultural Show for use on board his yacht. In Borneo they are attached to trees overhanging the coast, for loading vessels. They are also largely used in Cornish mines. They suspend chandeliers in public saloons. They are fitted on board the Royal Oak and the other iron-clad steamers. They lift the top of wagonettes and coach-houses, and, in short, wherever lifts are required with complete security in raising and lowering, the differential pulley blocks are employed with obvious advantage.—*Cor. Engineer.*

THE PATENT LAWS.—Resolutions were recently passed by the Inventors' Institute of Great Britain, to the following effect: that the inventor was entitled to remuneration for his labor, expenditure and skill as much as the author or artist to copyright for his book or work of art; that capital would not be embarked in promoting inventions unless profitable return for such capital is assured by the operation of law, such as is done by the existing patent law; that a good system of patent law tends to foster the trade and industry of the country, and to maintain its industrial position against the active pressure of foreign competition; that working men are especially interested in supporting the present law, by which they can not only safely exhibit their inventions in public, but reap the fruits of improved education and increased application of inventions.

SHIPPING OF GREAT BRITAIN—In the year 1868, the registered shipping of the United Kingdom (exclusive of river steamers) employed in our home and foreign trade, comprised the unprecedented number of 22,250 vessels of 5,516,434 tons, employing 197,502 men, exclusive of masters, viz: 20,525 sailing vessels of 4,691,820 tons, employing 153,840 men, and 1,725 steam vessels of 824,614 tons, employing 43,662 men. At the end of the year there stood registered as belonging to the United Kingdom 28,444 vessels of 5,780,530 tons, viz: 25,500 sailing vessels of 4,878,236 tons, and 2,944 steam vessels of 902,297 tons. This is the highest tonnage ever recorded. There was built and registered in the United Kingdom in 1868, 879 sailing vessels of 300,477 tons, and 232 steam vessels of 79,096 tons.

WAVE POWER.—An engineer of New York proposes to employ the waves of the ocean as a motive power for running mills, factories, &c. His plan is to build on the beach (at Long Branch, Rockaway, or elsewhere) a dyke several hundred feet in length, against which the waves of old ocean are privileged to break as wildly as they will, but are not to be allowed to recede. In the sea face of the dyke are the openings of conduits which conduct the water to a reservoir within the dyke. A canal from the reservoir re-conducts the water, by a circuitous route, to the ocean, to turn on its way the wheels of as many mills as can be built on the canal banks.

Deep Sea Soundings.—At a meeting of the New York Association for the Advancement of Science and Art, held June 14, Mr. Livingston Morse exhibited his recently invented device for taking deep sea soundings without the inconvenience and delay incident to the use of ordinary sounding lines. The apparatus is termed a "bathometer," and consists in a hollow cylinder of wood or sheet-metal containing a number of hollow glass spheres, which, being filled with air, constitute the floats by which the device is caused to return to the surface of the water after its descent to the bottom. The cylinder is ballasted in such a way that it will maintain an upright position in the water, and has a detachable weight affixed to its lower end. When dropped overboard, the weight carries the apparatus to the bottom, whereupon, by an automatic contrivance, the weight is detached and the cylinder rises to the surface. The time of ascent and descent being about equal and the rapidity of movement being ascertained by previous experiment, the period of submersion is a tolerably accurate index of the depth. The inventor, however, does not intend to rely upon this, but has provided the apparatus with a peculiar registering device by which the pressure of the water, and consequently the depth, is accurately recorded. The instrument is furthermore so contrived as to bring up a specimen of the bottom of the sea at the point where it struck.—*Am. Artizan.*

Water Deprived of Air—Boiler Explosions.—In reference to the well-established fact that water, after having been deprived of air as much as possible, either does not boil at all when heated, or does so with violent, sudden starts and concussions, some experiments have been made by Kremers, who observed that, in order to assist in expelling air from water, the addition of spirits of wine, in the proportion of one part of the latter to three of the former, is very useful. He cautions against a danger which exists when such a mixture is heated too rapidly, since it is very apt to boil over, especially after a portion of the spirit has evaporated. It is rather curious that, though both the water and spirits of wine were pure, the mixture when boiling should assume a greenish-yellow hue, which disappears again on cooling. The boiling-point of the fluid easily becomes as high as 109°. As a result of a large number of experiments, the author finds that water, as fully deprived of air as possible, may be heated as high as from 180° to 200° C., without boiling permanently.—*Quarterly Journal of Science.*

A New Freezing Mixture, which appears to be of considerable interest, has been described by Mr. Galletly. When citric acid and crystallized carbonate of soda, in powder, are stirred together, the mass gets into a pasty state, and in a short time becomes quite liquid. If equivalent proportions of the substance are used, the temperature falls from 60° F., to 8° F. The mixture, for a time, is full of air-bubbles, but soon becomes a clear, dense, syrupy fluid. The fluid obtained by mixing the powders becomes solid in a day or two standing in a corked jar. The solid mass has the appearance of set plaster of Paris or damp chalk. The addition of a very little water appears to prevent this setting into a solid mass; but the chalky-looking citrate lies a long time in cold water without being dissolved.—*Quarterly Journal of Science.*

Platinizing Copper.—In order to obtain a platinizing fluid capable of platinizing copper, yellow metal, and brass, add to a moderately concentrated solution of chloride of platinum, finely powdered carbonate of soda until effervescence ceases, next some glucose, and afterwards just so much common salt as will cause a whitish-colored precipitate. When it is desired to apply this mixture for platinizing, the objects to be treated are placed in a vessel made of zinc and perforated with holes, the vessel is then placed, with its contents, for a few seconds in the mixture just described, which, just previous to using, should be heated to 60° C. On being removed from the zinc vessel, the objects are to be washed with water and dried in saw-dust.—*Quarterly Journal of Science.*

Self-Registering Compass.—An instrument of this description, devised by Captain Albini, of the Italian Navy, and constructed by Messrs. Elliot Bros., of London, was exhibited at the late Conversazione of the Institute of Civil Engineers. It consists essentially of a compass, with a card carrying types at its periphery in such a way that, by an attached clockwork, an impression may be made at stated intervals on a band of paper, from whatever type is over a certain point at these times. Thus clearly an almost continuous record of the ship's course may be automatically produced.

Water Ballast Road Roller.—Messrs. Ames & Barford, of Peterboro', England, are building rollers, water tight, so as to be filled with water to increase the pressure when necessary. Besides securing in one roller a one, two, or three-horse implement at pleasure, the increased weight is employed directly on the surface of the land, with the highest percentage of crushing power, yet without increasing the friction on the bearings (and consequently the draught of the implement), as is the case when the old clumsy plan of loading the frame is resorted to.

Ventilation, Food and Health.—General Morin, in giving an account at the Academie des Sciences of the successful application of his ventilating apparatus in a large weaving factory employing 400 workpeople, and in which were lighted 400 jets of gas, observed that its advantage might be judged of from the fact that during October, November and December, 1867, when the ventilation was defective, only 15,000 kilogrammes of bread were consumed, while, during the same months of 1868, after it had been improved, 20,000 kilogrammes were required, being a gain of 25 per cent for the health and vigor of the operatives.

Wasted Coal Dust.—In Great Britain the quantity of coal dust remaining unemployed is calculated at 28,000,000 tons. Various methods have been attempted to convert it into useful fuel by compressing it into cakes, but the operation is not sufficiently remunerative. In Belgium they follow another plan, which seems to answer better. They mix coal dust with eight per cent of tar, and then press it into cakes, which are found to make excellent fuel for steam engines.

Artificial Lightning.—Professor Pepper has recently added to the apparatus of the Polytechnic Institution a monster induction coil, which furnishes a spark, or rather flash of lightning, 20 inches in length.

VAN NOSTRAND'S ECLECTIC ENGINEERING MAGAZINE.

NO. XI.—NOVEMBER, 1869.—VOL. I.

BOILER EXPLOSIONS.

ON THE OVERHEATING OF FURNACE CROWNS AND OTHER BOILER PLATES WHEN COVERED WITH WATER.

Report of Mr. FLETCHER, Engineer to the Manchester Steam Users' Association.

From "The Engineer."

Every one at all conversant with the working of boilers is aware that when they are allowed to run short of water, the furnace crowns are apt to become overheated, the plate to be bulged downwards or otherwise distorted by the pressure of the steam, and in many cases to be rent, from which cause explosions frequently arise. This is admitted on all hands, and the *rationale* is so simple that the whole must be at once apparent.

It is not, however, by any means so generally known that furnace crowns may be overheated and bulged out of shape—sufficiently so in some cases to cause an explosion—even when they are covered with an ample supply of water. Such, however, is unquestionably the fact, and I wish specially to call attention to the subject on the present occasion.

Overheating of boiler plates when covered with water has been found to arise from two causes—one, the too local action of an intense fire, the other the character of the feed-water.

Injury from intense firing sometimes occurs to boilers heated by the flames passing off from separate furnaces constructed of fire brick, as in the case of puddling furnaces at iron works, when the flames are too frequently allowed to impinge directly upon the boiler, in consequence of which steam is generated so rapidly that the water is driven off from the plates, and overheating ensues. This is more especially the case where the heating surface is a vertical one, so that the steam on rising forms a separate film between it and the water. Two explosions resulting from this cause may be referred to. One of these occurred at an iron works on the 9th of February, 1865, to an externally fired boiler of the upright furnace class, heated by the flames passing off from two puddling furnaces, as well as from a large fire grate. The particulars of this explosion were given in the Association's "Monthly Report" for February, 1865. Another explosion of a similar character occurred on the 7th of February, 1866, to a plain cylindrical egg-ended boiler, heated by the flames passing off from a mill furnace at a works employed in the manufacture of angle iron. Details of this explosion will be found in the Association's "Monthly Report" for February, 1866.

It is desired, however, on the present occasion to call attention more especially to those cases in which overheating of the plates, whether in externally or internally heated boilers, has occurred simply through the character of the feed-water, and not from any peculiarity in the mode of firing. The feed-water which is found to be more particularly productive of overheating is highly impregnated with carbonate of lime. It forms but little scale, and that seldom thicker than an egg shell, though perhaps in some cases it may be nearly equal to one-eighth of an inch. It deposits, however, a good deal of fine flour or dust, which is generally of a lightish color. As this dust is quite loose, a good deal of it is floated away with the water when the boiler is emptied, while the remainder is readily washed out, so that on account of the ease with which it is removed, and the light character of the scale, it frequently escapes attention. If grease be introduced into boilers in which this deposit is formed, the furnace crowns are found to give way, the plates to bulge downwards, and leakage to take place at the seams of rivets. The distortion of the furnace plates, however, does not, as a rule, take place suddenly; on the contrary, the crowns come down very gradually, progressing little by little day after day, though hard firing in many cases has an immediate influence. Grease is introduced into boilers in various ways. The feed-water is frequently heated by blowing the exhaust steam from the engines upon it, so that the grease in the cylinders is carried with the feed-water into the boiler, while, in addition, the discharge taps from the cylinders sometimes blow into the cistern from which the feed-pump draws, so that the boiler gets all the engine sewage. Blowing the exhaust steam upon the feed-water has another effect beside the introduction of grease. It is sometimes lost sight of how much of the deposit formed within boilers is lifted out of the water by the steam and carried through to the engines, and thus disposed of either through the exhaust pipe in high-pressure engines, or in the hot well in low-pressure ones. When, therefore, the exhaust is blown upon the feed-water, this deposit is returned to the boilers, and a constant accumulation takes place, more especially if blowing out be neglected. That the steam lifts the deposit, and carries it along with it, is clear from the fact that it is frequently manifested at the glands and other parts of the engines, and also is heaped up in the steam dome when there is a shelf on which it can accumulate. These shelves are formed when the shell plate at the base of the dome is not cut away to its full size. This forms an eddy in the current of the steam, and leads to the deposit being dropped on the shelf plate, as just stated.

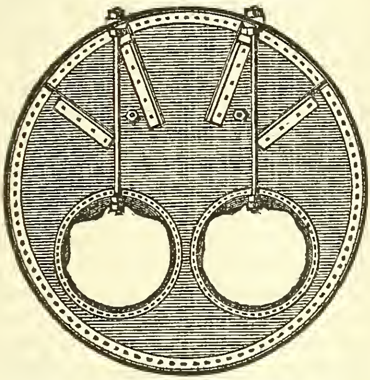
With regard to the manner in which this floury deposit affects the plates over the fire and leads to their injury, it does not appear to be necessary to suppose that this deposit becomes heaped upon the plates in order to lead to their overheating. It is doubtful whether it settles at all as long as the boiler remains in active work; while, were it to do so, it would settle where the ebullition was the least violent, and thus not on the furnace crowns of internally fired boilers. Possibly this fine floury deposit, by thickening the water, interferes with the due escape of the globules of steam, so that they are kept longer in contact with the plates over the fire than they should be, and thus the intimate contact of the water with the plates becomes interrupted, and overheating is produced. This may perhaps be illustrated in the following way: Clear water placed in a clean saucepan may be briskly boiled over a fire without foaming over, but if a little meal be dropped into it, or the water exchanged for milk, the globules of steam are no longer able to escape freely, and in their struggle they upheave the whole mass, and vomit a portion of it into the fire. Such is thought to be somewhat the action that takes place within a boiler charged with this fine floury deposit. The globules of steam imprisoned in the water lift it from the plates in their struggle to escape, and thus gradual overheating takes place in proportion to the character of the water and the intensity of the fire.

I am not desirous, however, of entering too minutely upon the precise manner in which this floury deposit leads to the overheating of the plates; suffice it to say that the results are indisputable, that numbers of boilers have been injured by it, and whatever may be the precise *modus operandi*, it appears to have the power of preventing that intimate contact of the water with the plates which is essential for carrying off the heat with sufficient rapidity, so that although they may not be made red hot, yet they become sufficiently overheated to lose a portion of their tenacity, when bulging under pressure ensues. Numerous instances of this have come before my notice, the particulars of some of which may now be given.

No. 1. The first of the cases that may be referred to was met with about the close of 1862, and occurred to a boiler fed from a well sunk near the river Mersey, in the neighborhood of Birkenhead. The boiler was of the ordinary Lancashire class, having two furnace tubes in which the fires were placed, while its length was about 20 ft., its diameter 6 ft. 6 in. in the shell, 1 ft. 10½ in. in the furnace tubes, and the load upon the safety-valve 40 lbs. per square inch.

This boiler had been found to give way again and again at the furnace crowns, the plates bulging down out of shape, and repeated repairs had taken place in consequence. The plates over the fires had been taken out and renewed with those of Lowmoor iron, which had every appearance of being of first-rate quality. Also each of the furnace crowns had been lashed to the top of the shell by three vertical stay rods, but the plates persisted in bulging downwards notwithstanding, and came down between and all round the points of support, as will be seen on consulting the accompanying cut, Fig. 1.

Fig. 1. Transverse Section.



Under these circumstances I was requested to examine the boiler and advise the owners as to what had better be done. Immediately on drawing off a little water from the glass water gauge I attributed the injury that had occurred to the furnace crowns to the fine deposit contained in the feed-water, and recommended a scum trough for blowing out from the surface of the water, in order to rid the boiler of this deposit. In answer to inquiries the owners did not think they were admitting any grease to the boiler, and had such confidence in the feed-water, which appeared so clear before it was pumped into the boiler, that I was unable to persuade them to adopt the simple expedient of a surface blow-out apparatus. One cause after another was assigned for the injury, and it was supposed that as the boiler was worked night and day, that the water supply had been allowed to run short at night time, and that the deflection of the plates was due to a series of minor neglects of this character. On one occasion the owners felt sure they had at last detected the source of the mischief. They discovered that the fireman, anxious to get away quickly on the Saturday evening, had started to blow off his boiler before he raked out the fires, in consequence of which the furnace crowns were laid bare with the fires still in, and thus became overheated. In confirmation of this it was stated that it had been frequently observed on setting to work on Monday mornings, that these deflections had been increased, so that the chain of evidence was supposed to be complete. It was soon found, however, that the bulging was too persistent to be accounted for in this way, and the owners, rather than adopt the simple expedient of putting in a scum trough for blowing out the deposit, which there is little doubt would have remedied the evil, resolved on condemning the boiler altogether and on putting in a new one.

The new boiler was of larger dimensions than the old one, the diameter being 7 ft. in the shell instead of 6 ft. 6 in., and 2 ft. $7\frac{1}{2}$ in. in the furnace tubes instead of 1 ft. $10\frac{1}{2}$ in., while the tubes were strengthened at the ring seams of rivets with encircling hoops, which had not been the case in the old boiler. With this new boiler, though not fitted with a surface blow-out apparatus, the same difficulty was not experienced as with the old one, which arose from the fact that the superior size of the new boiler enabled it to do its work more easily than the other, and thus with more gentle firing. As long, however, as the feed is of the same character as it was in the other boiler, the same tendency remains, and it will only be necessary to make the new boiler do as much work for its size as the old one did to lead to the furnace crowns being again disturbed, though doubtless they would derive considerable assistance from the encircling hoops, so that but little bulging of the plates might take place, though leakage would occur at the seams of rivets.

In this case the water was not analyzed, as it was on subsequent occasions, but it may be stated that it left a fine floury deposit of a very similar character to the cases mentioned below, and which were found to consist of from 70 to 80 per cent of carbonate of lime.

No. 2. Another very similar case of the failure of furnace crowns was met with in May, 1866. It occurred in the neighborhood of London, to a Cornish boiler fed with the New River Company's water.

This boiler, I was informed, had failed at the furnace crowns, and repeated repairs been resorted to. These, however, had such little effect that one boiler after another had been laid down, till some three or four boilers had been ruined in the course of three years; while one of the boilers had received a new flue tube. Added to this, experiments had been tried by altering the steam dome, and, altogether, the owner informed me, the affair cost him £700. Disheartened with these repeated failures, he was persuaded to exchange the internally fired boiler for an externally fired one, with a couple of return tubes running through it, which he had just laid down at the time of my visit.

On making an examination of the boiler I found that it contained a good deal of fine floury deposit of a light color, and that the feed-water was heated by the injection of the exhaust steam from the high-pressure engines, so that the grease from them passed through into the boiler. I called the owner's attention at once to these facts, and explained to him that these were the causes of all the trouble he had experienced. He urged by way of objection that prior to the last three years the boiler had worked for a considerable time with the same water, and with the feed heated by the exhaust steam, without giving trouble, and therefore argued that the fault could not be with the water or with the grease discharged from the engines. This objection appeared at first sight difficult to meet, but on inquiry it was found that about three years before then the work became too severe for the engine, when its power had been doubled by the addition of a new cylinder, which gave the boiler more work to do, and necessitated its being more severely fired. This at once made the whole matter plain. The tendency had existed all along, but had not been developed till the fires were pressed.

The following is an analysis of the deposit in question:

Carbonate of lime	73.87
Carbonate of magnesia	4.59
Oxide of iron and alumina	7.07
Organic matter	3.15
Sand silica alumina	11.32
	100.00

N. B.—This was a fine dry powder of a slate color, difficult to wet with water.

It will not escape observation that this floury deposit contained as high an amount of carbonate of lime as 73 per cent, and, simple as it appears, it was through the presence of this fine flour or dust that the four boilers referred to above were ruined, and the expenditure of £700 incurred.*

In the new boiler a good surface blow-out apparatus was adopted, and the boiler was frequently blown out at the bottom as well as from the surface of the water. This proved sufficient to remove the difficulty, though the credit was wrongly given to the change from the internally fired boiler to the externally fired one. Externally fired boilers are effected by this description of feed-water as well as internally fired ones, which will be seen from the next case of inquiry.

No. 3. A third case was met with in June, 1867, at a colliery in the neighborhood of Ruabon, North Wales. In this instance six new plain cylindrical egg-ended externally fired boilers failed within six weeks after they were set to work, giving way at the plates over the fire. These boilers were 5 ft. 6 in. in diameter, 36 ft. long, made of plates three-eights of an inch in thickness, and worked at a pressure of 40 lbs. per square inch. The owners threw the blame of the failure of these boilers on the makers, attributing it to the quality of the plates or workmanship, and consequently a dispute arose, and I was requested to make an examination. On doing this I found that the plates over the fire were of Lowmoor iron and of good quality, and that the fault did not rest with the boilers but with the feed-water, which formed, as in the previous instance, a fine floury deposit, consisting to a great extent of carbonate of lime, while it was heated by the exhaust steam from the engines, and thus charged with grease, in consequence of which, as in the previous cases, the plates over the fire had been overheated and bulged down out of shape, while, in addition, leakage had taken place at the seams of rivets. The manager was unwilling to accept so simple an explanation of the difficulty, though he had previously received a similar opinion from another engineer, and been advised that he must either change the feed-water or give up heating it with the exhaust steam, so as to prevent the introduction of grease to the boilers. Though ridiculing the recommendation, he had nevertheless diverted the exhaust steam from the feed-water, when he found that the result justified the explana-

* From a table compiled by J. Atfield, F. C. S., Demonstrator of Chemistry at St. Bartholomew's Hospital, it appears that the New River Company's water, with which this boiler was fed, contains 19.78 grains of solid matter per gallon. Also that the amount of carbonate of lime is greater than that of any other ingredient, and equals 7.82 grains per gallon.

tion given and remedy proposed. Time showed that overheating did not recur, and the boilers worked on without further trouble.

The following is an analysis of the deposit formed within these boilers, and which, I believe, was taken from them before the arrangement for heating the feed by the exhaust steam was given up, so that at that time grease was admitted:

Carbonate of lime	75.26
Sulphate of lime	10.02
Carbonate of magnesia	8.78
Oxide of iron and alumina	.47
Insoluble matter (sand, &c.)	2.68
Organic matter	2.79
	100.00

N. B.—This sediment was a white powder and smeled of tallow. By digestion with ether, grease was extracted and collected.

The following is another analysis of the deposit taken from these boilers subsequently to the last specimen, and after the practice of heating the feed-water with the exhaust steam had been discontinued, when the boilers were fed with cold water:

Carbonate of lime	84.10
Sulphate of lime	2.25
Carbonate of magnesia	8.73
Oxide of iron and alumina	1.41
Insoluble matter (sand, &c.)	1.98
Organic matter	1.53
	100.00

N. B.—The organic matter did not contain grease.

It will be observed the grease was detected when the feed-water was heated by the exhaust steam, but not after that practice was discontinued.

In addition to the above, further analyses were made at a later date, both of the fine floury deposit and of the scale:

Floury Deposit.

Carbonate of lime	80.00
Sulphate of lime	6.08
Carbonate of magnesia	12.44
Oxide of iron and alumina	.98
Sand, &c	.50
	100.00

Scale.

Carbonate of lime	77.40
Sulphate of lime	9.52
Carbonate of magnesia	10.90
Oxide of iron and alumina	1.22
Sand &c	.96
	100.00

The following is an analysis of the water with which these boilers were fed:

The total solid matter left on evaporating a portion of the water amounted to 45.15 grains per gallon. This consisted of—

	Grains per gallon.
Carbonate of lime	23.75
Sulphate of lime	1.57
Sulphate of soda	4.33
Common salt	2.63
Carbonate of magnesia	5.18
Organic matter and loss	2.69
	40.15

Note.—The carbonates of lime and magnesia are kept in solution by the presence of free carbonic acid. If this is neutralized by the addition of lime, a portion is precipitated. By this means nearly one-half the total matters in solution may be removed. Also in boiling the water, before evaporation commences, a portion is precipitated.

From the above analyses the high proportion of carbonate of lime will be seen in each case:

Analysis No. 1 gave—Carbonate of lime	75.26
No. 2 gave—Carbonate of lime	84.10
No. 3 gave—Carbonate of lime	80.00
Mean result	79.78 per cent.

From this it appears that the mean result was nearly equal to 80 per cent of carbonate of lime contained in the fine floury deposit.

It should be added that at the same colliery there was another range of plain cylindrical externally fired boilers, which had been working for a number of years without failing as the new ones had done. The manager, therefore, pointed to this fact in support of his view that the new boilers were at fault and not the feed-water, since the feed-water appeared to him to be as good in one case as in the other. To settle this question an analysis was made of the water with which the old range of boilers were fed, as well as of the deposit formed within them, in order that a comparison might be instituted, when the following was found to be the result:

Sediment.

Carbonate of lime	22.00
Sulphate of lime	63.78
*Magnesia	14.07
Oxide of iron and alumina	.09
Sand, &c	.06
	100.00

*This would be equivalent to 20.17 carb. magnesia.

Scale.

Carbonate of lime	10.17
Sulphate of lime	72.94
Carbonate of magnesia	15.89
Oxide of iron and alumina	.63
Sand, &c	.37
	100.00

The following is an analysis of the water:

A portion of the water evaporated to dryness, left a residue amounting to 90.3 grains per gallon. This contained—

	Grains per gallon.
Carbonate of lime	.15
Sulphate of lime	16.93
Sulphate of soda	51.55
Common salt	2.93
Carbonate of magnesia	17.11
Magnesia	1.22
Organic matter and loss	.41
Total	90.30

N. B.—As this water is concentrated by evaporation it becomes alkaline.

The addition of lime gives a precipitate amounting to nearly one-third the total matter in solution.

Boiling the water causes no precipitate. There was a deposit of organic matter at the bottom of the jar which contained the water.

The results of the analyses of the feed-waters of the new and old ranges of boilers, as well as of the sediment, will be the more easily compared on reference to the following table:

New Boilers which failed after six weeks' working.

Percentage of carbonate of lime in fine floury deposit	79.78
Grains of carbonate of lime in a gallon of water	23.75

Old Boilers which worked for years.

Percentage of carbonate of lime in fine floury deposit	22.00
Grains of carbonate of lime in a gallon of water	.15

From this table it will be seen how different were the characters of the waters by which the two ranges of boilers were supplied, and how much more carbonate of lime was contained in the one that fed the new boilers, which failed after six weeks' work, than in the one which fed the old boilers that worked on for years, while it corroborates the view that the failure of the new boilers was not due to their material or workmanship, but to the fine floury deposit formed by the feed-water.

No. 4. The fourth case of injury to furnace crowns through the use of a feed-water forming a fine floury deposit, came under my notice in August, 1867, and occurred in the neighborhood of Lancaster, to a range of three Lancashire boilers measuring about 28 ft. in length, 7 ft. in the diameter of the shell, and 2 ft. $7\frac{1}{2}$ in. in that of the furnace tubes, which were strengthened with T iron hoops at each of the ring seams of rivets, while the blowing-off pressure was about 60 lbs. per square inch. In this case, though the feed-water was drawn from a neighboring stream, which was perfectly clear to the eye, these boilers were found to give repeated trouble at the furnace crowns, the plates bulging down, and the ring seams straining and leaking.

The fault had erroneously been attributed to the construction of the boilers, in consequence of which the encircling hoops had been removed and the furnaces renewed with ordinary lap-riveted plates. This alteration was clearly in the wrong direction, and the plates soon bulged, and the seams soon leaked again as badly as ever.

The accompanying cut, Fig. 2, will show the nature of the distortion of the furnace crowns in this case.

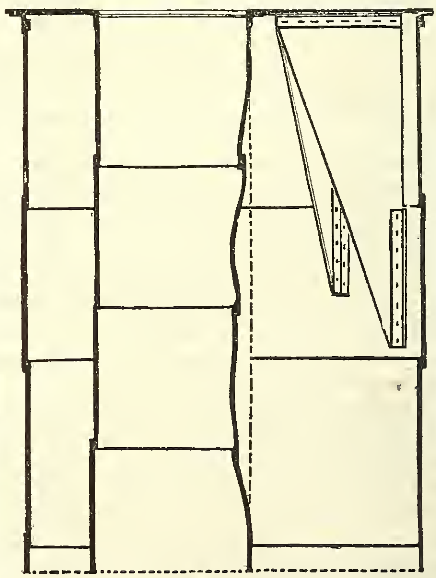


Fig. 2. Longitudinal Section.

At this juncture I was requested to make an examination, and on getting inside one of the boilers, found that it contained a considerable quantity of light floury deposit, very similar to that met with on previous occasions, and already described, while in addition the feed-water was heated by the exhaust steam from the engines, and thus charged with grease. Though a surface blow-out apparatus was fixed to these boilers, it was quite neglected, the connection between the internal collecting trough and the scum tap being broken off, so that it was rendered useless, while the boilers altogether had been very carelessly looked after. These facts were faithfully reported to the manager of the works, coupled with the recommendation that the practice of heating the feed-water by the injection of the exhaust steam should be at once discontinued. But this view of the case by no means proved acceptable. The manager was resolved to have the boilers condemned, and not their treatment, or that of the feed-water. The following analysis, however, of the feed-water and sediment formed by it, shows how similar they were in character to the previous cases referred to:

Sediment.	
Carbonate of lime	84.210
Sulphate of lime	1.447
Carbonate of magnesia	3.991
Iron-peroxide, alumina	1.811
Silica-sand	1.441
Moisture and volatile matter	7.100
	100.000

N. B.—The volatile matter seemed to be of an oleaginous nature, and could not well be estimated.

Water.	Grains, per gallon.
Carbonate of lime	11.228
Sulphate of lime	3.840
Carbonate of magnesia	2.224
Chloride of sodium	2.460
Silica	.550

Total residue, 20.440. Hardness before boiling, 13.5°. Hardness after boiling, 4.5°.

N. B.—The water was clear, slightly acid, and contained but a trace of iron. It has no particular solvent action on iron.

Looking at the above analysis, there can be no question that the character of the feed-water and the introduction of grease, coupled with the practice of allowing the sediment to accumulate in large quantities in the boilers, was the cause of the injury to the furnace crowns, as in the cases previously referred to; while it may be added in confirmation, that after examining these boilers I was informed that one, if not more, of the fusible plugs had been blown out, though covered with water at the time, which is a clear evidence that overheating had taken place. Trying, however, as the feed-water was in this instance, the injury to the furnace crowns would have been materially reduced, and probably avoided altogether, had the apparatus for blowing out from the surface of the water been kept in good order and regularly used.

It may also be stated that at the time of my visit I strongly urged that the boilers should be gently fired, since, under the circumstances, hard firing might bring the furnace crowns down in two hours. I had but just returned to Manchester when the manager wrote me that another of the boilers had failed at the furnace crowns, and the works in consequence were at a standstill. Hard firing is an important element in these cases of injury to furnace crowns with waters containing this fine floury deposit.

No. 5. The fifth case which may be referred to, occurred in Sunderland, to a boiler of the patent double-furnace conical water tube class, and my attention was called to it in January, 1868. This boiler had been found to fail repeatedly at the plates and seams of rivets in the furnaces, in consequence of which frequent repairs had been had recourse to, and, supposing that the injury to the boiler was due to expansion of the parts, and to too much rigidity, a hoop of bridge rail or horse-shoe section had been worked out of Lowmoor iron, and introduced at one of the ring seams of rivets in each of the furnaces, in order to give elasticity. This, however, proved of no avail, the furnaces again gave trouble and bulged inwards, when some strong stays, lashing the furnaces to the shell, were put in, somewhat as in the case of No. 2, and as illustrated in Fig. 1.

At this juncture the owner of the boiler, who was a corresponding member of this Association, saw me with regard to it, and from his sketch of the shape in which the furnaces had given way, the case appeared very similar to those already mentioned, while it turned out on inquiry that the feed-water contained a good deal of carbonate of lime, and that it was heated by the exhaust steam, and thus received the engine sewage. I laid the facts of the previous cases before the owner of the boiler, and on his return he had the feed water changed, when the bulging of the furnace crowns ceased, while, it may be added, that he found on reference that the difficulty with the furnace crowns had commenced with the use of the feed-water in question, so that this afforded a double proof of the cause of the injury, No. 6. The sixth case which may be mentioned, and to which my attention was first drawn about March, 1868, gave as much perplexity as any one of them.

It occurred to an ordinary Lancashire boiler in the neighborhood of Manchester, while the feed-water, which was drawn from a well sunk on the premises, was heated by the exhaust steam from the engine. The boiler measured about 24 ft, in length, 6 ft. 9 in. in the diameter of the shell, and 2 ft. 3 in. in the furnace tubes, while it was worked at a pressure of about 55 lbs. on the square inch. This boiler had been originally constructed for experimental purposes, in consequence of which some steam pipes from 10 in. to 12 in. in diameter were carried through it from one end to the other, which thus served as longitudinal stays to the end plates. As these complicated the boiler they were removed, and gusset stays substituted for them.

Shortly after this the furnace crowns were observed to leak. Whether this had commenced before the removal of the pipe stays just referred to, or not, is difficult to ascertain; at all events, the owner attributed the difficulty with the furnace crowns to the removal of these pipes and the introduction of gussets in their place. This clearly, however, had nothing to do with it, though it was not very apparent what was the real cause. After repeated minor repairs, however, were found useless, the furnace tubes were taken out altogether, the front half of them entirely renewed and strengthened at two of the ring seams of rivets with T iron hoops, while the front end plate of the boiler was also renewed.

The manner in which the repairs were executed appeared on examination to be satisfactory, nevertheless the boiler only worked on a few weeks before leakage again commenced. A consulting engineer was then called in, who gave it as his opinion that the fault was in the workmanship, and that the overlaps had not been well drawn up. The defective seams were therefore again repaired, the old rivets cut out, the holes rimered, and fresh rivets put in.

Just at the time that the boiler was restarted, a number of practical working boiler-makers had a meeting, and discussed the cause of the continued and mysterious leakage that had occurred to this boiler. One of them strongly objected to the encircling hoops, and to these he attributed all the injury, stating that he had a similar boiler under his charge, which was never out of trouble, but always leaking and needing repair; while he considered such a boiler was as good as an annuity to the boiler-mender, and that the man who was charged to keep the one under consideration in order, would never be in want of a job. At length the meeting unanimously resolved that encircling hoops prevented any expansion of the furnaces, and that it was against all the known laws of nature for boilers constructed in this way to keep tight; and further, that within three weeks leakage would set in again, and the works wonld have to be stopped for further repairs. This decision was communicated to the owner of the boiler, and surely enough, within the appointed time the boiler commenced to leak once more. At this the owner was quite disheartened, and regretted that he had not had the boiler entirely renewed rather than repaired.

In a long conversation with the owner at this juncture, it transpired incidentally that when his men first got into the boiler after letting off the water, they found some loose fine dusty deposit within it, when it at once occurred to me that this case might be similar to the others previously recorded in this report. This had not been suspected before, since the furnace crowns were not bulged out of shape, but merely strained at the seams of rivets; while in answer to inquiries it had been stated that the deposit altogether was of a very inconsiderable and trivial character. I therefore explained to the owner my suspicion that all the trouble he had experienced was due to the feed-water, and recommended him at all events to give the boiler a trial with the Manchester town's water, instead of that drawn from the well, a recommendation, it may be added, that had already been made, as a matter of precaution, but had not been thought worthy of adoption. Though he had no faith in the remedy proposed, it was so simple that he consented to try it. The boiler was at once washed out, and the next morning started to work with the town's water. From that day the trouble was over. The boiler worked on satisfactorily for several weeks, and after being slightly caulked so as to remove the effects of the old leakage, it was perfectly sound; and though the T iron hoops, which were decided at the meeting of the boiler makers to be "opposed to all the known laws of nature," had not been removed, the boiler has worked on to this day without giving further trouble, and promises to do so for the next seven years.

The following is an analysis of the sediment, from which it will be seen that carbonate of lime is the predominating ingredient, though it does not form so large a percentage as it did in the previous cases, which it is interesting to notice in connection with the fact that in this boiler the furnace plates were not bulged, but merely strained at the seams of rivets:

Carbonate of lime		38.960
Copper		trace.
Carbonate of lead		1.790
Sesquioxide of iron		5.005
Alumina		4.456
Sulphate of lime		4.490
Carbonate of magnesia		1.216
Magnesia		11.847
Phosphoric acid		trace.
Chlorine		trace.
Sand and silicic acid		17.977
Fat	7.375	10.742
Other organic matter	3.367	
Moisture		2.219
		98.702

The deficiency is partly due to the given percentage of carbonate of lead being too small, and to the traces of alkalies, copper, phosphoric acid and chlorine.

When the boiler continued to work on satisfactorily week after week and month after month, simply by exchanging the well water for the town's water, the owner could not entertain any further doubt on the subject; and on recollecting the changes made in his works from time to time, and remembering how the well had been deepened to increase its supply, he was also able to trace a clear connection between the use of the well water and the leakage of the boiler.

This shortly received a striking corroboration. In the course of the long drought that occurred in the summer of 1868, the supply of the Manchester Waterworks, as all in this locality will remember, began to run short, especially for engine purposes, so that for one afternoon the owner was obliged to fall back on the well water, when, though he tried the experiment for a few hours only, the boiler at once commenced to leak as before, so that he gave up the well water once more, and resolved never to return to it again.

This case, though not so severe as some of the others mentioned, is perhaps the most interesting, from the great perplexity which arose with regard to it, and the conclusive manner in which it was cleared up.

No. 7. The seventh case was met with near Carlisle, in July, 1868. The boilers in this instance, which were of the ordinary Lancashire type, and strengthened at the ring seams of rivets in the furnaces with T iron hoops, drove a condensing engine, and were fed from the hot well. The length of these boilers was about 30 ft., their diameter in the shells 7 ft., and in the furnace tubes 2 ft. 8 in., while the load on the safety-valve was about 50 lbs. per square inch.

These boilers gave way, as in the previous cases, at the furnace crowns, in consequence of which the owners reflected on the makers, and the makers, knowing they had delivered sound work, could only account for the failure by supposing that the boilers had been neglected, and the water supply allowed to run short.

On making an examination, I found that the deposit within the boilers was of a fine floury nature, like that already described in the previous instances, though the quantity was not so great, neither were the furnaces so severely distressed. The following is an analysis:

Carbonate of lime	69.39
Iron (peroxide)	2.17
Alumina	2.03
Sulphate of lime	2.39
Carbonate of magnesia	3.38
Silica and sand	10.73
*Organic matter	7.56
Moisture	2.35
	100.00

From the above analysis, it will be seen that the feed-water was very similar to that met with in the other cases previously referred to, though it will be seen that the percentage of carbonate of lime is scarcely so high, which possibly explains the fact stated above, that the furnace crowns were less distressed than usual.

No. 8. The eighth case that may be referred to, was met with in August, 1868, and occurred to a couple of boilers laid down near the river Mersey, in the neighborhood of Widnes. These boilers were of the ordinary Lancashire type, and were but just new, yet they had failed repeatedly at the ring seams of rivets of the furnace crowns, when the old rivets had been cut out, the holes rimered, and new rivets inserted, but without success.

Under these circumstances, the makers of the boilers called upon me, when, in answer to inquiries, it appeared that the feed-water was heated by the exhaust steam from the

*Containing 2.95 of fatty matter.

donkey engine, and that the deposit was of a light floury character. I at once recommended that the exhaust should be diverted from the feed-water, and on this being done, the difficulty with the furnace crowns was overcome. In about a month afterwards, the boilers were reported as working satisfactorily, although they had never stood for more than forty-eight hours before.

The following is an analysis of the sediment, which, as in the previous cases, shows a predominating proportion of carbonate of lime:

Carbonate of lime and magnesia..	83.33
Sulphate of lime...............	1.17
Alumina and iron..............	4.25
Silica..........................	7.40
Oily matter.....................	.25
Organic matter.................	3.60
	100.00

It may be added that further cases have been met with in the neighborhood of Widnes, and that in December last two other boilers came under my attention, the furnaces of which were bulged out of shape from the same cause as that referred to above.

It is worthy of note that three different cases of injury to furnace crowns from this fine floury deposit have been met with in the neighborhood of the Mersey, and within a few miles of Liverpool.

I have gone into this subject at some length, because it is one not generally understood. It will be seen that the cases of injury referred to were not confined to any peculiar locality, but were met with in the neighborhood of London, Lancaster, Carlisle, Birkenhead, Sunderland, Ruabon, Widnes and Manchester, so that they were widely scattered over the country. It can scarcely be doubted that for the want of understanding this subject, many cases of misapprehension between boiler owners and boiler makers must have occurred, and the blame of leakage at the seams of rivets in the furnaces, attributed to defective workmanship, or overheating, through neglect of the attendants, instead of to the feed-water. It is trusted that the general diffusion of information on this subject will prove of practical value to boiler makers and boiler users, and that the number of examples given will be considered sufficient to establish the fact that both in externally and in internally-fired boilers, the plates over the fire may be overheated and bulged out of shape even when covered with water.

MODERN ARTILLERY AND TACTICS.

From the "Army and Navy Gazette."

There can be few studies so interesting to a military man who loves his profession as the various modifications of tactics that have, from time to time, been forced, as it were, upon the different armies of the civilized world. From the days when the crossbow had to give place to arquebuse, when the latter was superseded by the heavy muskets of the seventeenth century, when, after progressive modifications, the flint-locked Brown Bess became the weapon of the day, when the old smooth-bore percussion reigned supreme for a time, and was put aside for the rifle which, only two or three years ago, was in its turn superseded by the breech-loader—through all the different phases of small arms, as well as large ordnance improvements—the art of war has always, and will for ever, be progressive. The valiant officers, the plucky, all-enduring armies of the Peninsula and of our Indian campaigns in the commencement of this century never dreamt of any improvement upon the cumbersome flint musket, that missed fire at least once in every dozen shots, and if, when it hit the mark aimed at, was supposed to have almost worked a miracle. The arms we use have changed, and tactics have changed with them. The ordnance of to-day is as unlike what we fought the Sikh campaign, or went through the Indian mutiny, or made our way into Sebastopol with, as the smooth-bored flint musket was to the breech loaders now in use. And it must stand to reason that the art of attack and defense of one great body of soldiers against another must be modified in proportion to the arms of the day. At Waterloo it would have been quite possible for cavalry to get over two thousand yards of ground in a charge, and not be subject to danger from more than one volley of the infantry square they attacked. In our time the same troops would be decimated three or four times ere getting home to their work. And so it has been, only in a much greater degree, with artillery. "It seemed," wrote Villani, when speaking of the employment of cannon at the battle of Crecy, "as if God thundered, and that with His thunder there was a great massacre of people and a frightening of horses." And yet, for more than a century after the time that this historian wrote about, the artillery could hardly be called movable. Even under Francis I. of France, the ordnance of the period—mere pop-guns of our own days—followed armies with such difficulty, and so slowly, that the infantry maintained the tactics of the past age, and formed in heavy masses in front of the enemy's guns. Little by little, as the ordnance in use got better and more precise, it became necessary to protect infantry behind walls, or, when in the open field, to deploy battalions so that the artillery fire could not do much damage, even when it penetrated the ranks. Gustavus Adolphus, Condé, Turenne, the Marshal Saxe, the Prince d'Anhalt-Dessau, Frederick the Great, and even our own Malborough, gradually changed the formation of infantry. The real use of this arm only became fully known when the Great Frederick had changed altogether its mode of working. At the battle of Molwitz this great soldier-king learnt what could be done by foot soldiers who fired rapidly and well—that is, well for the days in which he lived. From that time infantry became, throughout Europe, by far the most important arm of the service. It was henceforth seldom massed together in columns. Its lines were extended, and rapidity was introduced into all its movements. With a small army and a very numerous enemy, Frederick was obliged to strike out for himself a new mode of tactics. He avoided as much as possible meeting numbers by numbers, or trying to conquer by material strength, and tried to introduce an improved style of firing, and rapidity of movements, by which an engagement could, when needful, be avoided quite as quickly as it could be brought on. Under him, also, the artillery began to assume the importance it has ever since maintained in modern warfare. The guns were made more movable, and men began to see with wonder something like a system of drill and tactics used when working ordnance to the front, the flank, or the rear. And so on down to the time when, the then, Gen. Bonaparte began to be talked of as a leader who seldom led the way to anything except victory. As the French Republic changed into the Empire, and as the hand of its great chief was against every one, and every one's hand against him, the tactics of the day changed, and became nearer to what they were in our own service within the memory of living men. The bayonet gradually became an arm much used by all infantry. Perhaps no soldiers took to it as kindly as did our own troops; but, still, it effected great changes in the mode of fighting in all armies. In France this weapon became more popular when the campaigns in Algiers worked such an immense change in the army of that country. For close upon forty years France has had work cut out for her troops in the school of war which she founded in Northern Africa. An entirely new type of the French soldier has arisen to be the model man of her service. Individual fighting, looser formations, a manner of achieving an end, no matter how, so that it was achieved, became the rule more than the exception in the army, of which the Zouave is the picked soldier. In our own service, notwithstanding several attempts to introduce the modern French system of almost separate working on the part of each fighting man, we have, with certain modifications, maintained our more compact formations, and our reliance of each soldier upon the whole company or troop to which he belongs, more than upon his own individual exertions. We have made changes certainly, but they have neither been rash nor very considerable. That our system, so far, suits our men much better than greater changes would do, there can be as little doubt, as that we have held our own whenever and wherever we have taken the field. Whether we shall have to make further changes, or whether our infantry movements are rapid enough for the arms with which our enemies, as well as ourselves, will in future carry, is a question which admits of discussion. But there can be little doubt but that by degrees a very considerable modification in some of our tactics must take place. When an average military marksman can hit an enemy at 800 yards seven times out of ten, it becomes that enemy to be more active, either when advancing or retiring, than when a similar feat could only be achieved once in perhaps a dozen shots.

The great difficulty connected with the modifications of modern tactics seems to be that we are yet only in a state of transition as regards firearms. In all that regards both breech-loaders and field-guns, we have advanced far, but shall probably—we might say certainly—advance much further. Even, however, if progress has reached its limits in the perfection of arms of precision, it becomes a matter of wonder how far future cavalry can ever be used against unbroken infantry, when armed with the breech-loaders now in use, and taught to fire as the ordinary average of regiments are. There is a point beyond which courage is mere rashness, and pluck on the part of the commander becomes a wanton waste of life. Would not such be the judgment passed upon any cavalry leader who would launch his regiment or brigade against an infantry square armed even as our own and other European armies are at the present day? Against infantry broken or in retreat, against the same arm when thrown into confusion by some blunder on the part of their commander, against the cavalry of the enemy, or against artillery when not unlimbered, dragoons must ever prove of the utmost service, and no army in the field could do without them. So it is when feeling for an enemy, when pushing to the front, and anxious to bring on an engagement, the cavalry arm must ever be present to do that which it alone can effect properly. But unless some change, of which as yet we know nothing, takes place in the firearms of the world, we shall, probably, never again hear of cavalry being used to charge infantry squares as in old time.

Again, it is an open question how, with the present improvements in artillery, either infantry or cavalry can ever be used in the open field to silence a battery of guns. At the present day the artilleryman, although he cannot load as quickly, fires with almost as great precision as the infantry soldier. In the advance of an infantry brigade against a battery, unless circumstances were exceptional and much in favor of the former arm, there would be no formation left by the time they reached their destination. This, as a matter of course, can be rectified very much by rapidity of movement on the part of the infantry soldier, and in this change, as we imagine, will be found one of the chief alterations of modern tactics. Much greater quickness in advancing; the "double" taking the place of our present quick time; and a certain reckless dash, which will tend greatly to abolish steady formations, will probably supersede many of the movements now in use. But the chief change will most likely be a rule by which no arm of the service will ever, or very seldom, be employed alone. Brigades will probably not be composed of cavalry nor of infantry alone, but each one, and perhaps, indeed, each regiment, have a certain force of cavalry and infantry attached to it. In the state of transition which we find ourselves to be, and in which every army in Europe must find themselves to be, these speculations on future tactics must be more or less vague. But it can hardly be said that they are improbable, far less impossible. As we advance in the excellence of firearms and of ordnance, it seems likely that each branch of the service will depend more and more on one another, and that the smallest commands will become what divisions of the army have been hitherto—a mixture of cavalry, artillery and infantry, and that every officer who aspires to command even a regiment must be able to know how to command and when to use other arms of the service as well as that to which he himself belongs. At any rate, as far as it is possible to see, this appears the only possible solution of what is the military mystery of the future. But for the changes to become visible, or for any definite rules upon the subject to be practicable, we must wait for the experiences of the next European war.

THE ESTIMATES OF CONSULTING ENGINEERS.

From "The Engineer."

Possibly in one case out of fifty, probably not in one instance out of five hundred, does the actual cost of a heavy job coincide with the estimate previously prepared by the engineer. This proposition is so well understood, that it is accepted as an axiom, that the total cost of a bridge, or an embankment, or a mill, or a factory, must be in excess of the estimate; and as a kind of precautionary measure intended to defend the engineer from the charge of incompetency which may be brought against him, and the capitalist from the consequences of not properly counting the cost before he begins to build, a something, known as "a margin for contingencies," is always added to every estimate, and forms, indeed, an integral part of it. This margin, however, seldom or never suffices; for, as a rule, the outlay always exceeds not only the calculated cost, but the calculated cost and the margin as well. If the excess be moderate, no very serious consequences may ensue; but it must not be forgotten that the excess has not unfrequently been so large as to entail the total ruin of the capitalist or capitalists; or at least to reduce the profits which he or they expected to realize to a nominal return. An estimate right within 20 per cent of the actual cost is, however, regarded as a very good estimate, and one reflecting much credit on the engineer and all concerned. Yet this 20 per cent is to our minds sufficiently unsatisfactory, and bears small testimony to the value of existing systems—or want of systems—of estimating the cost of work. It ought to be, and no doubt is, possible to ascertain beforehand with much accuracy, how much money will be spent in carrying out any undertaking to a successful termination. This is proved by the fact that estimates, perhaps accidentally, do now and then agree very closely with the actual expenditure; and it is worth while, we think, to inquire why such an agreement is exceptional instead of being the rule.

The reasons why estimates and expenditure so seldom coincide, are two in number. In the first place, the engineer does not accurately know how much work has to be done; in the second place, he does not know how much the doing will cost. As regards the first, it is possible that the engineer may not be at all to blame. The preparation of a complete design for a complicated structure, such, for example, as a cotton mill, is all but impossible. When the drawings come to be made, a host of small things are certain to be left out, simply because they cannot be put in to any reasonable scale on paper; they are to be supplied afterwards. It is known in a kind of way that they will ultimately be needed, but no one thinks of wasting time in ascertaining what they will really cost, and of what they will consist. Almost from the first moment they are put out of sight, and to nothing more than to such trifles as these will the proverb "out of sight out of mind" apply. The so-called trifles, however, make themselves disagreeably prominent before the work is completed. They must be supplied and paid for, and they not unfrequently constitute an ominous feature in the bill. We shall not pretend to define in what trifles of this kind consist. Every engineer who has prepared an estimate for work differing from anything he has estimated for and carried out before, will be likely to class trifles, using the word in our sense, under a different head. No engineer will deny their existence, their costliness, or the influence which they exert on estimates, and this much admitted, our proposition is granted.

Under certain circumstances, however, we find the engineer very much to blame, because he totally overlooks the necessity which exists for the construction of essentials, or relegates important features to the region of real trifles. The result of such negligence, or errors of judgment, may be disastrous. We recollect one case in which a factory was put up, and boiler and engines put down at a cost of about £10,000. It was known that no water from river or stream was available. A shallow well was therefore sunk, and from this water sufficient for mortar, &c., was obtained during the progress of the works. The insignificant cost of this well was included in the estimate. By the time the factory was completed, however, it was discovered that not nearly enough could be had from it for the purposes of manufacture. A very large further outlay—nearly £1,000—was incurred in sinking the well deeper, without leading to any satisfactory result; and, finally, rather than abandon the factory altogether, £2,000 more were spent in laying a main and opening a cutting from a river at a considerable distance. Here the original estimate was increased nearly 50 per cent by a single mistake. Such cases are, of course, very exceptional; but it is not at all exceptional to find estimates based on the first cost of machines delivered at the works, not one farthing being added for erecting them; the value of the bricks required based on their price in the field, the trifling question of carriage being totally forgotten, and such like. Such mistakes as these will cause actual outlay to exceed estimated cost with great certainty, and it is the easiest thing in the world to be guilty of them. None, indeed, but those who have had to prepare estimates for large undertakings, can tell how much trouble, and what unceasing watchfulness is required at every step to avoid error.

Even if we suppose the engineer to have ascertained with the utmost accuracy everything that can possibly be required, from the steam engine to the time-taker's clock, it does not follow that his estimate must be right: the second class of error to which we have alluded to may come into play. It is one thing to know what you want to buy, quite another to know what it will cost. An engineer may determine with strict accuracy how many yards of earth must be taken out to prepare an engine foundation, but his estimate of the cost of taking it out may be altogether wrong, for it is not the quantity of earth to be removed, but the whole cost of removal, that affects the precision of the estimate. In the first place, he may not have taken the trouble to ascertain the cost of labor, or the nature of the soil; in the second, water may come in on him, and defeat all his calculations. In estimating for machinery, the engineer is peculiarly apt to fall into error. He sets down the cost of engines and gearing at so much, and on going into the market finds that no manufacturing engineer will touch them at the price. The reason is simply that the manufacturers, knowing that estimates generally err on the wrong side, put on a "margin for contingencies," on which the would-be purchaser has not calculated at all. He puts down £2,000, we will say, for engines and boilers. He has, perhaps, worked out the cost of these very carefully on paper. The maker does the same thing, and comes, perhaps, to nearly the same result, to which he immediately adds 50 per cent, not only for profit, but as margin, and to cover the chance of loss. Both parties are right in their own way, but our engineer's estimate is all wrong. Nor is this the only difficulty which those who prepare estimates have to contend against. It is sometimes almost impossible to say what work ought to cost, prices vary so much in different districts, and among different makers. We may state a case in point which recently came under our own notice: An engineer putting up large works, required some heavy castings. Before preparing his estimates, he wrote to some of the leading firms in the country asking the prices at which they would execute the work. Before a week was over he found that he could have his castings at any price, from £12 to £5 7s. 6d. per ton, and, in any case, sufficiently good for his purpose. Some of our readers may say that this gentleman adopted the proper plan, and that estimates based on actual tenders in this way, could not be far wrong. This supposition, however, is true only within certain limits. We may cite a case in point which came under our own notice a few years ago. An engineer had occasion to order some very heavy gearing. He got two or three tenders for the castings, and he accepted the lowest tender. A moderate quantity of wrought iron work, in the shape of plummer block bolts and nuts, wheel boss hoops, &c., was also required. This he did not think it worth while to ask a price for, regarding it as a trifle. The work was delivered, and so was the bill; on examining it the engineer discovered that so much had been charged for the wrought iron, that instead of obtaining the gearing as a whole, at the cheapest, he had paid at the dearest rate. The other tendering parties would have charged a little more for the castings and a great deal less for the wrought iron, that was all.

We have said enough, we think, to show that consulting engineers are called upon to discharge a difficult duty in the preparation of estimates; a duty, we may add, often so badly paid for that he is sorely tempted to slur over his work and add a good margin for contingencies to cover his short comings. It is not to negligence, however, that we are inclined to ascribe the thoroughly unsatisfactory state in which the practice of estimating now is, but rather to incapacity. There is no good treatise on the subject, although there are plenty of "price books" containing forms of tender and specifications. The art of estimating forms no part of the present course of engineering instruction, either in the office or the college. When a young man can take out quantities and prepare an estimate at the rate of so many rods of brick work so much, one steam engine fitted complete so much, &c., &c., he is considered to have his education finished in this direction, as far as the office or the college is concerned, while in point of fact he is no more competent then to form an accurate estimate than if he had never been taught engineering at all. Those instructors of youth who doubt this statement, will do well to test its accuracy thus. Let them procure the bills furnished to and paid by any large manufacturer or ironmaster for the erection of any given premises or machinery. Then let them lay down the prescribed conditions to three or four of the most advanced pupils they have got, ask them to send in estimates elaborated from their own brains, aided by such treatises as they can find on the subject, and compare these estimates with the actual bills paid. They will see that our statement, that no pupils are taught anything practically about estimating, is confirmed with startling force. Is it not just possible that the test we have indicated might be made a valuable feature in the courses of engineering colleges, and the method of instruction adopted by private teachers? We think so; and we further think that there would not be the slightest difficulty in introducing it. A little less mathematics, and a little more instruction as to what things really cost, would be a change for the better in the young engineer of the period.

BAD AXLES.—Certain railroad companies are putting in passenger axles which they know to be made *at one piling, from old rails only.* Such trifling with life is frightful.

STEAM GAUGES.—Very few years have elapsed since Mr. Daniel Kinnear Clark called steam gauges on locomotives luxuries, not necessities. At this moment we believe there is not a locomotive in Great Britain working a railway carrying passengers which is not fitted with a steam gauge. The truth is that when Mr. Clark wrote, the world, with the exception of a select few, knew only of the cumbrous mercurial gauge, or the yet more imperfect manometer. The Bourdon gauge had only been talked about by users of steam power in general, and it was quite natural that Mr. Clark, in common with the great body of his professional brethren, should regard all known gauges likely to suit a locomotive as mechanical quiddities—things of the border land which lies between true mechanical science and *quasi* mechanical humbug, and reject them accordingly. The manufacture of gauges has, however, become a great trade, and now not only every locomotive engine, but almost every boiler and every portable engine in the kingdom is fitted with one. The steam gauge has asserted itself, so to speak, and by its obtrusiveness it has forced itself into that position where criticism begins. Where this last may end, only the makers of steam gauges can say.

A steam pressure gauge can only be used for three purposes. The first is to tell accurately the pressure in a steam boiler at any moment when the water is hotter than 212 deg.; the second is to tell variations in the steam pressure from time to time; and the third is to bring in money to the makers. We regret to say that the last point is more studied than the others; indeed, so much studied that the value of the modern mercantile steam gauge as an index of the pressure within a boiler at any moment is very small indeed. There is nothing like facts to prove assertions; and as we plainly repeat that the modern steam gauge of commerce is a very worthless instrument, it is right that we should adduce facts in proof of our statement; and as these facts tend to show what maker deals best with his customers, and who serves them worst, our statements should prove all the more valuable. It is well known, or should be well known, that under ordinary conditions the Royal Agricultural Society will not permit a greater pressure of steam to be used within the limits of their show-yards than 50 lbs. per square inch. Every exhibitor intending to get up steam must, therefore, submit the gauge with which his engine is fitted to the Society's engineers, Messrs. Easton & Amos, who test the gauges and return them with a certificate that the boiler may be worked at a pressure of so many pounds by its own gauge, which is equivalent to 50 lbs. per square inch. We have taken the trouble to examine nearly every certificate granted by Mr. Amos this year at Manchester, and to compare each certificate with the gauge. The following table shows the result:

No. in catalogue.	MAKER OF GAUGE.	Pressure equivalent to 50 lbs.
2	Schaeffer & Budenberg	47

Here we have 52 gauges by recognized makers, and out of the whole number only 9, or less than 18 per cent, are correct. This is a fact which, we fancy, will startle our readers, and we trust open the eyes both of guage makers and guage buyers to what they are selling and making.

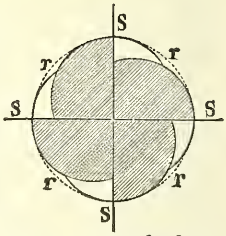
It may, of course, be urged that the gauge used by Mr. Amos in testing those of the exhibitors is not accurate. But even if this were true—and it is not—there would still remain an immense discrepancy between the tested gauges themselves. No want of accuracy in the standard gauges can affect this part of the question. If we suppose, for example, the standard gauge to be 5 lbs. too high, denoting 50 lbs. when there was only 45 lbs., then we should have Smith right; but, on the other hand, where will Schaeffer be? One of his gauges, under such conditions, would be 11 lbs. wrong, and none of the others will be less than 3 lbs. wrong. When it is borne in mind that steam gauges, properly used and properly fitted, play a very important part in the prevention of explosions, all this want of accuracy comes out in a very bad light. Nor do the figures we have given show the worst. Gauges were brought up to Mr. Amos to be tested which were 30 lbs. wrong, and which he, very properly, would not allow to be used at all. Let us hope that such imperfections are the result of ignorance or carelessness rather than of a determination to ignore every other condition save economy. Twelve months will elapse before the gauges used by the agricultural engineers of Great Britain are again publicly tested. Is it too much to expect that we shall have a different record to place next year before our readers?—*Engineer.*

IMPROVED SHAPE OF SCREW-TAPS.

By Prof. O. Beylich.

Condensed and translated from Polyt. Centralblatt.

The "Propagation Industrielle" contains an interesting article on a method of making screw-taps of a new and improved shape, as practiced in the large machine-shop at Graffenstaden. The screw-taps are there turned and cut in a turning-lathe provided with a peculiar mechanism, the effect of which is, that the pieces produced by turning and by the cutting of the thread are not circular in section, but of a shape more favorable to a successful working of the tap when finished. It is generally acknowledged that the screw-taps as made heretofore, conform but imperfectly to what must be expected from a good cutting-tool. The action of an ordinary tap does not produce regular chips; it does not leave room enough for them, nor allow the oil easy access to the working-edges. Thus they produce an unnecessary amount of friction, and become rapidly blunt and worn. Some improvements have been made in this respect. But the cylindrical or conical shape of the nucleus of the tap has been retained. No tap, however, having a nucleus of a circular section, can ever work as advantageously as any other good cutting tool; for it does not suffice that the edge be sharp. The tool, besides, ought not to touch the surface of the screw to be cut, but just with its edge; and the cutting edge ought to be free at the back, and must therefore have a tooth-like shape. To make the action of the tap as perfect as possible, not only the edge formed by the intersection of the upper and lower surfaces of the triangular thread must be eccentric, but also both surfaces of the thread must recede eccentrically from their respective cutting edges. This is effected by the method of cutting taps as adopted at Graffenstaden.



The annexed engraving may give an idea how this is done. The fine dotted outline is circular, and indicates the section of a piece of steel turned off in the ordinary way. The above-mentioned peculiar mechanism, however attached to the turning-lathe at Graffenstaden, does not turn the piece circular, but in a shape indicated by the full drawn outline of the annexed figure, so that the piece obtains a wavy surface. The cutting of the thread is afterwards done in the same manner and with the same mechanism. Thus a screw of a wavy section is produced with alternating swells (*s*), and recesses (*r*), each of which extends over the whole length of the piece. The number of swells corresponds to the number of teeth intended to be given to the tap. Our engraving shows four of them. To finish the tap it is only necessary to cut out one half of each swell by a planing or a milling machine, to a depth corresponding to the required length of the teeth. Thus taps are obtained of a section about as indicated by the hatched surface in the engraving. The planes of the cutting-faces pass through the axis of the tap. S.

PATENTS AND PATENT LAWS.

By W. Bridges Adams.

From "The Society of Arts Journal."

The word "monopoly" is one of exceeding ill odor with the great mass of the community, and to affix such a name to patents is considered a very clever move on the part of their opponents. It catches the public ear, and the public is very apt to take things for granted, that appear to conform to its interests. What is a monopoly? A privilege conferred upon special individuals, for their own advantage, to the disadvantage of the community. At first sight, numerous private rights appear to be monopolies—land, mines, forests, rivers, the raw material of the world, which are the property of the whole human race, as tenants in common; and for individuals to possess and own them as private property, is simply a concession granted, because they will produce a generally greater fruit by the process of individual enclosure, than by a general scramble. The conversion of the raw material into useful forms, by the operation of the human brain and human hands, creates another kind of property, giving the raw material far greater value by mental and physical labor, labor which would not be given unless the owners could reap some of the fruits of it by an enclosure of the results of their own brains or hands as their own property. Origination of new and useful ideas and forms, producing something better and more useful than has been produced before, is the most valuable kind of labor, and, therefore, the world, in proportion as it becomes civilized, gives exclusive property, for a longer or shorter time, to the producers of the ideas, and goes still further in giving hereditary rights to long-continued industry.

Language is common property, but the author of a book, putting language into new forms, in combination with ideas, is endowed with what is called "copyright" for a term of years, a monopoly, in short, for the reason that, without that monopoly, the books would not be produced, or only a very few books would be produced by a few wealthy and powerful persons; and the very title of the book is also a monopoly. Another person produces a picture which has a high value, and the right to reproduce that picture by engravings or photographs, or other means, is reserved to him. Another produces new combinations of musical sound, and the multiplication of copies of this music is as much his own property as the original. Another produces a piece of sculpture, with the same results. Another produces a new design for furniture, or patterns for dress, or other manufacture, and that is as much his own, with the exclusive right to sell it entire or in copies, as though it were the corn and cattle of the farmer, or the fruit of the orchard owner, or the vegetables of the market gardener.

This monopoly goes still further. The style and title of a firm is private property; and, as if to guard against the contingency of the same Christian and surname in combination being used for competition by a namesake, trade-marks were invented to insure the monopoly, and every possible means are resorted to to prevent a trader's individuality from being trenched on by his neighbors. Yet more: a proprietor of a newspaper, with no individuality, and who purchases all his wares ready made from other persons, has the exclusive right to a particular word or combination of words out of a dictionary, which, if he be the first to assume, no one can appropriate till he chooses to abandon his right.

Throughout all these things it is the right of property which the law jealously guards, mental or other. But for this law, a large mass of mankind would disguise themselves in their neigbors' likeness, to reap the profits accruing from their neighbors' reputation.

What are called patents, are mental originations, multiplied in matter, and the law professes to confer on the originator the sole right to use and sell them to the public for the course of fourteen years. Some of these originations are very popular, and an enormous trade grows up, from which large profits accrue, and it is very commonly an article not of real importance to the welfare of the community that makes the largest profits; but whatever it may be, trade rivalry is excited, and any means are resorted to for evading the patent, without payment to the inventor. Everything previously known in the trade is at the disposal of the rivals; but the Naboth's vineyard they covet is the new thing which the public prefer, either for its superiority or its cheapness, and which has been the production of the inventor's brain. So they set to work to defame him, to deny his originality, to call him a monopolist, to decry his invention, to try and invade it by inferior methods, and, finally, to take advantage of inefficient laws, to plunge him into costly trials that may ruin him, and put the invention out of use, if they cannot appropriate it to themselves without paying anything for the cost of its production.

A few years back, an attempt was made to decry and abolish patents at the meeting of the British Association, and now once more an attempt is making to obtain a huge monopoly, under pretext of abolishing another —not a monopoly as of old in the case of the corn-laws, for the benefit of landlords or landowners, but for the supposed benefit of trade-lords and capitalists generally. Large manufacturers, material converters, and similar people, desire to get the use of brains without paying for them, or to keep things as they are. It is not a case of patentees against the community, as their opponents endeavor to make out, but a case for the community itself, as interested in progress, against wealthy traders who would keep down all progress, if by so doing they could keep up their own profits. It is the case of the community, in behalf of the active brains that work for them with mental capital, and without material capital, against the dull and inert brains, with material capital in masses, which at present, stimulated into competition by the restless brains around them, lead an uneasy life, and would fain become the slaveholders of the active brains, and prescribe limits to their labors under their own control, and for their own imaginary benefit. It is an attempt to create an hereditary trade aristocracy, by taking away the fulcrum through which clear brains rise into the possession of material capital, and their owners elbow the inert rich from their seats. And, not uncommonly, it is those who have grown rich upon patents who are the most strenuous opponents of other men's patents.

The common ground of opposition is that patents impede progress. If they did, that would be sufficient reason for their abolition. But assertion is not demonstration. It is asserted that the patent is a monopoly which no one but the owner can use. Quite true; but so is land a monopoly which no one but the owner can use, the difference being that the patent is a monopoly for fourteen years, and the land forever. The patent is a fourteen years' monopoly of individual brain-work, the land monopoly is that of the material works of the Creator. If the land were the property of the State, the rentals would belong to the general community as a tax fund, and the community gives it to individuals on the supposition that they will manage it better for the general benefit of the community than the State could, the rental being the payment for their trouble. The patent is a limited property, the land is an unlimited property, both conferred by the community, and capable of resumption, if demonstrated to be mischievous to the community.

The brain-worker can only, in the case of patents, operate by the agency of matter, the property of the landlord, who exacts a large share of the brain-work in return for the use of the matter. But the brain-working patentee has no monopoly. He is exposed to the competition of all others using the landlord's matter, or the materials of the Creator, save in the patentee's particular mode. And no sooner has he achieved a success, than other inventors are immediately at work to eclipse him, to the benefit and advantage of the public; and it is notorious that, even in the case of a successful invention not superseded by another improvement, commonly half the fourteen years' term expires before an invention is brought even into limited use.

The large manufacturer has his choice of patents by competition amongst brains, saying nothing of the stored-up records of lapsed patents at the Patent Office, which he rarely has recourse to, save to compete with, and defeat, something new, which a rival manufacturer has produced under a patent, and turned to profit. It is well known that few manufacturers will embark in new things without the protection of a patent, for the reason that money must be expended experimentally, and that rivals lie in ambush to reap the profits in competition, without outlay, and consequently can undersell the originator, and for this reason the records of lapsed patents in the Patent Office are not resorted to, but remain dead letters.

It has been sought to make a distinction between copy-right and patent-right. There is none; they are alike, in their integrity, original emanations of the human mind, and we may be quite sure that the abolition of patents would soon be followed by the abolition of copyright in books or works of art. Copyright in designs is copyright in a representation. Patent-right is copyright in form, and utility, and methods of production; whether brain imagination be multiplied in printed books, or in music, or in engraving, or artistry, or design, or theatrical exhibitions or shows, or stamped on matter under what are called patents, it is the same pro cess of expressing mind in matter as an origination; and as the originators are comparatively few in number, it is desirable to cultivate them, and give them enclosures of mental domains wherein to have free scope for the exercise of their various arts, for precisely the same reasons that the enclosures and private ownership of land—a common property—is granted to the producers of food, and for other purposes.

It is simply the system of bad laws to which all the evils of patents are traceable. There was a time when, amongst the manufacturers of printed fabrics, all new designs were kept secret as far as possible till the moment of issue, and all were busy bribing, or trying to bribe, their neighbors' designers. The Act for Copyright in Designs, abolished this system of piracy, and with it the secrecy. Were patents abolished, one of the results would be a return to secrecy in all small things, a closing of manufactories against inspection, and a general dearth of information to mechanical periodicals, while improvements, involving a large outlay of capital, would cease to be made, unless perchance in government establishments.

If the spread of knowledge be a national advantage, the inducement to secrecy by the abolition of the patent—*open*—would be a serious evil.

Amongst the reasons alleged for the abolition of patents, one is, that the patentees gain no advantage—being ruined by opposition and lawsuits, in case of the invention being successful.

This is the greatest farce of all, as if land property would be safer than brain property, were it protected by as bad and inefficient laws as patents are subjected to, and as if there were any difficulty in making as efficient laws for patents as for books and designs, were only influential men interested in bringing them to pass, and lawyers not interested against them.

Another allegation is, that the great mass of modern patents are useless. If they are useless they need not be coveted. If impedimental, they certainly must supply something useful. But it is again alleged that they are frivolous. But is not trade itself widely frivolous? Yet what merchant is there who despises anything frivolous, provided only large profit be mixed up with it? What is more frivolous than the majority of theatrical farces, yet what is there more carefully guarded against piracy? But, say the objectors, patents are granted for things not new, and merely serve as an excuse for lawsuits. That simply means that the law and practice have not yet been fitly established. Some say that patents are becoming so numerous that they cannot keep count of them, and so unwittingly infringe them. This is not logical. The patentee might as well object, "The great manufacturers make so many new things without giving me notice, that I cannot keep count as to my originality." This complaint on the part of manufacturers only proves that they manage their business badly. It is surely part of the business of a great manufacturer to know of everything produced in his special art, and, therefore, he should keep a book of patents, as regularly as his price list, with a managing clerk to it. He can, at small cost, have all the specifications in his trade supplied to him as fast as they come out, and he can index them, and mark out all the real novelties and utilities, and put them to use by agreement with the owner. It is said that every British subject is bound to know all the laws, or take the consequence of breaking them, and certainly a British manufacturer is bound to know all the patents in his trade as part of his business.

All existing knowledge and manufacturing experience up to the present time, is the joint property of the whole nation, less certain things protected by patents expiring in fourteen years. But these patents are the "Naboth's vineyard," coveted by the lords of trade.

But they may fairly say that amongst the numerous patents there are many fictitious ones, involving lawsuits, and thus deterring them from the use of what is really common stock. That is to say, the patent laws are bad laws, so bad, that were all laws equally bad, the nation would be in a condition of anarchy. To abolish the patents, instead of to reform the law, would be a precedent upon which we might abolish all laws.

Let us begin at the beginning. Patents are virtually granted for something new and useful, thereby to teach the public, and the reward for such teaching is a fourteen years' exclusive right. What, then, is "novelty?" There is nothing new under the sun, absolutely. The patent is really granted for something new to the existing generation, as an inducement for a skilled man to bring it into use. The title should, therefore, be put on a similar footing to that of land. A piece of unowned land, unclaimed for thirty years, becomes the property of whoever may occupy it, and forever. Therefore, supposing patents to be in the interest of progress, absence of public use for thirty years should constitute a claim to anything useful as a novelty for fourteen years, or such time as might be deemed equitable.

Everybody of legal age should be competent to apply for and obtain a patent, but as any preliminary examination and refusal might involve an accusation of nepotism or a contingency of error, not afterwards to be amended, it is desirable that protection should be granted, if desired by the applicant, after pointing out to him the defects; and that the specification, after completion, should be put on open, not secret trial, by a competent judge, in the presence of the patentee, and the original fees should cover this cost. It is not desirable that a model should be put in at first, as involving the employment of workmen and the risk of discovery before protection is granted; and models being expensive, it is not fair to encumber the patentee with costs.

The affirmation of the patent by the court, should preclude all further litigation as to title and right, the court itself taking the initiative, or acting at the instance of a complainant.

Pecuniary damages should be dealt with by a magistrate, as in the case of copyrights, or by the ordinary courts of law.

Fictitious patents abolished by the court, would cease to be a nuisance in the hands of sharking pretenders. There are very few patents requiring deep thought to apprehend them when produced, or any length of time, when legal quibbling is abolished.

An inventor should not be bound to license other persons, for the reason that they might be rivals, only taking a license in order to damage his invention in public reputation. If an unreasonable man, he would damage himself by limiting the use. If a manufacturer, he might be interested in selling at the lowest price without royalty profit, and thus as a small capitalist he might compete with great capitalists, by securing the trade in a better article.

If the invention were a small item in a large machine, and the inventor required an unreasonable royalty, that would simply be a stimulus to other inventors to make other improvements, and this would be clearly in the interest of the public.

In cases where the subject of a patent has been in private use previous to the specification, unknown to the patentee, it would become a question for the court to decide as to whether the public had been kept out of the knowledge furnished by the patentee, and if so, the patent should be confirmed, subject to the use of the first user, but without giving to him the right to license earned by the patentee by his publication.

No excuse of ignorance of a patent should be admitted as a plea or mitigation of infringement, because, with the full means of obtaining the records of the Patent Office, the ignorance must arise either from willfulness or negligence.

Patents are the Magna Charta of the material progress of a nation, by the agency of the rich brains of men, poor in practical capital, who can mould matter to man's uses after new and useful fashions, just as copyright is the Magna Charta of the nation's progress by the agency of men of rich brains, who can mould language to men's uses after new and useful fashions. When laws shall be made to take away this charter, and throw brains into common stock, one of the sources of England's eminence, her true equality, will have departed from us, and the trade lords will find that their vitality has departed with it. They will compete with each other with increasing competition and lowering profits, till their trade becomes as wild land, which no one cares to cultivate. They will then find that the fourteen years mental enclosure, which induces men of thought to bring forth new things, is also one of the processes essential to profit, and that by abolishing it they "kill the goose which lays the golden eggs."

Trade-marks are the legitimate arms and quarterings of a trade aristocracy, guarantees of honesty in execution, and which become valueless as a manufacture becomes debased. They are monopolies in one sense, as they enable the owners to keep to themselves a large trade, so long as they keep up their character, and the law now jealously deals with their infringers. The patent is also a trade-mark, exclusive for fourteen years, enabling the owner to establish a reputation for originality and improvement, and to keep his reputation when thrown into competition with rivals. And with patents confined to the owners of manufactories, that would simply be establishing a caste of veritable monopolists.

The question has been dealt with thus far simply in the interest of the public, regarding the inventor merely as a part of the public. But the true inventors are more than this—they are a select body of students, who foresee those things that the manufacturing men of routine pass by blindfolded, and thus stir them up to action; and the public is deeply interested in caring for these men, and guarding their interests as their own. From the trade point of view, the mere manufacturer only looks to the profit per-centage attainable by the raw material into wrought, and would work up the whole raw material of the land, and afterwards throw it into the sea, if realizing the percentage thereby. It is this class of men that deteriorates our national manufactures in money competition, that makes rails as brittle as cast-iron, and delights in shoddy; that has no perception of, or care for progress, but only for money.

It is not thus that the greatness of England has grown; nor is it of the highest importance that inventors should reap enormous fortunes, albeit trifling in proportion to the gain to the general community; but it is desirable that they should be in the unanxious position requisite for the most advantageous pursuit of their studies and experiments, as a result of their own labors.

The nation in which all classes of its people can rise in succession, according to their faculties and cultivation, from the lowest position to the highest, must ever be more powerful than a nation of castes, and a nation without laws efficiently protecting mental as well as physical property, must degenerate into a land of castes—or robbers.

There is yet another allegation on the part of opponents of patents. Having to pay a royalty in England, other nations paying no royalty can undersell them. It is scarcely so, for other nations are as desirous of having patents as English people are. Of the two republics, America and Switzerland, the former abounds with patents, the latter has none. The reason is, that in the former case they are a function of the Federal government, in the latter of every separate canton, rendering patents a practical impossibility. But citizens of Switzerland expatriate themselves, and get patents here and elsewhere, and it is probable that the patent branch of legislation will be transferred to the Federal government, and Switzerland will cease to be an exception to other civilized States.

With a climate and condition like that of England, where workmen live longer and do more days' work in every year than in most other countries, it is impossible that she should be undersold in her indigenious manufactures, so long as her materials shall endure. Capital embarked in the growth and training of a workman, is profitable in proportion to the length of his working life, and the faithful and honest work produced.

The assumption that every patentee only forestalls a number of other persons, who would have discovered or planned the same thing, may or may not be true, but this does not concern the public. What the public want is individuals who will work, and teach in the best mode he can, something new and useful; and daily experience tells us that such individuals cannot be obtained save on the condition of thereby obtaining a specific sphere of action involving their own benefit as well as that of the public. Let any one try if, by simply publishing a new and useful thing, he can get it taken up unless he can offer an exclusive right with it. Neither is there any probability in the assumption that all the principles of action have been discovered, and that the details are in every one's hands. The tree of universal knowledge is yet far from having been plucked, and it is to be desired that the men of science, as well as the men of practice, should be not only recognized but rewarded, as the benefactors of the community—not rewarded, as M. Chevalier proposed, by the State, but by the community. We do not want political inventors, with a Government reward as a compensation for something other than an invention, and with their own friends to apportion it. We want for them the only true appreciator, the public.

There is no difficulty in remedying all the evils complained of in the present practice of patents. Forms of specifications can be prepared, embodying everything that is required to be stated, leaving no loopholes, and preventing verbiage, giving an exclusive privilege to make something useful, and leaving it open to competition to make something still better. The life of the inventor patentee is no lazy life. He has the public for a master, and a very exacting master too, content with nothing but the best or the cheapest, and ever ready to abandon its idol of to-day for its idol of to-morrow, succeeding each other in constant following. What do the long list of patens in the same arts mean, save that the human brain works only from step to step, eclipsing yesterday by to-day, and thus preparing the way for the morrow, a vantage-ground being gradually attained, till the process culminates in an apparent perfection, at last found to be no perfection, when a fresh start is made to a new elevation. By the sweat of the brain within his brow, the inventor diminishes human labor and the sweat of many brows, for his own profit is out of the service he renders to mankind, who will not pay for anything they do not appreciate as useful or pleasant. No State reward is needed as a stimulus to this kind of labor. The inventor only asks to be let alone to reap the crops he has himself sown, secure against depredation.

It was Prince Albert by whom the amended Patent Law, then being worked out by the Society of Arts, was finally urged, and it was Lord Granville who brought in the Bill and passed it through Parliament, in the course of a very few days, because it was believed that only thus could a number of latent inventors amongst mechanical men be brought to light for the benefit of the Great Exhibition. It was this Bill which, by reducing first cost, multiplied the number of patents, and put poor men on a level with capitalists. And it would appear that non-inventive capitalists would rather be without these patentees, and would prefer to buy up their inventions for their own purposes, and so limit the public choice in the market. Patents give a large market for constant improvements, which would not exist without them. All the large manufacturing towns and cities of England may be said to be built upon patents, and were patents abolished, the result would be similar to that of the abolition of the Edict of Nantes; the imaginative brains would depart from England, and settle down in the countries wise enough to understand their true interests. Viewed from the monopoly point, the wisest course the manufacturers could take would be, not to abolish patents, but to enhance their cost. If patents cost £5,000 each, with efficient laws to maintain them, every poor man would be shut out, and patents would become the practical monopoly that the manufacturers insist on calling them. But the motive would thus be too gross.

The subject cannot be too widely discussed, nor the facts elicited too clearly, for we cannot as a nation afford to risk our prosperity in order that a small number may grow richer at the general cost. We want a general diffusion of wealth, and not a greater aggregation in masses. Large manufactures tend to the growth of quantity rather than quality. Small manufactures tend to the growth of quality, and that diffusion of wealth so largely trenched on of late by the gigantic establisments which permit only two classes, the very rich and the very poor. The higher classes, living on incomes, the result of land or hoarded wealth, are deeply interested in the question, for it is a question of property right; and in the diffusion of property, rather than in its concentration, lies its safety. The convenience or profits of manufacturers is but a small consideration, as well as the convenience or profits of inventors. The national prosperity is the real question at issue. Shrewd Frenchmen tell us that we began patents some fifty years before them, and, therefore, they have never been able to overtake us. Were we now to abolish patents for fifty years, our human energy would be expended in producing original workers for all other nations, and excluding our own.

THE BRITISH COAL SUPPLY.

From the opening address of Sir Wm. G. Armstrong, before the Institution of Mechanical Engineers at Newcastle.

The subject of coal follows, naturally, a notice of the steam engine, and has a special interest for us, in a locality celebrated, since its earliest days of coal mining, for the production of that invaluable mineral. England, with her innumerable steam engines and manufactories, is more dependent upon coal for the maintenance of her prosperity than any other nation, and the question of the duration of her coal-fields now very properly occupies the attention of a Royal Commission. The investigations of the Commission are not yet completed; but so far as they have gone, the results are reassuring. I concur in the probable accuracy of the announcement lately made by two of my fellow commissioners, that the total quantity of coal in this island will prove to be practically inexhaustible; but until the complicated details of quantities collected by the Commission have been put together, and expressed in totals, it is difficult to judge with certainty or accuracy on the subject.

Although the duration of our coal may, geologically speaking, be practically unlimited, we have still to consider the important question, how long will England be supplied with coal as good and as cheap as at present? We have unquestionably made greater inroads into our best and most accessible coal beds than other nations have done into theirs; and if foreign coals should grow better and cheaper, and ours dearer and worse, the balance may turn against us as a manufacturing country long before our coal is exhausted in quantity. It is clear that our stock of good coal is very large; but most of it lies at great depths, and one of the most important questions the Royal Commission has to investigate is the depth at which coal can be worked with commercial advantage.

The chief obstacle to reaching extreme depth is the increase in temperature which is met as we descend. I am justified, by ascertained facts, in saying that this rate of increase will, as a rule, prove to be not less than one degree Fahrenheit for every 20 yards in depth, and there is reason to expect that it will be even more rapid at greater depths than have yet been attained. The constant temperature of the earth in this climate at a depth of 50 ft. is 50°, and the rate of increase as we descend is to be calculated from this starting point. Adopting these figures, you will find that the temperature of the earth will be equal to blood heat at a depth of about 980 yards, and, at a further depth of 500 yards, mineral substances will be too hot for the naked skin to touch with impunity. It is extremely difficult to form an opinion as to the maximum temperature in which human labor is practicable, in the damp atmosphere of a mine, and it is almost equally difficult to determine how much the temperature of the air, in the distant parts of an extremely deep mine, can be reduced below that of the strata with which it is brought in contact. It is certain, however, that the limit of practicable depth will chiefly depend upon the mechanical means which can be provided for relieving the miners of the severest part of their labor; for maintaining a supply of sufficiently cool air at the working faces of the coal, and for superseding the use of horses, which suffer even more than men from highly heated air. For the relief of labor we must look to coal-cutting machines; for improvement of ventilation to exhausting fans; and for the superseding of horses to hauling engines driven by transmitted power.

The employment of coal-cutting machines, worked by compressed air, conveyed into the mine by pipes, is already an accomplished fact, and when the difficulties and the objections which usually adhere, for a considerable time, to new mechanical arrangements are removed from these machines, they will probably attain extensive application. One of the earliest attempts at coal-cutting by machinery, was described by the late Mr. Nicholas Wood, at the former Newcastle meeting of this Institution, and all the really practical results as yet obtained date from that period. The cooling influence of the expanding air as it escapes from these machines will be a collateral advantage of considerable importance in the hot atmosphere of a deep mine. The air discharged from the pneumatic coal-cutting machines now in use in the Hetton Colliery, escapes into the mine at a temperature of seven degrees below freezing, and the cold air from each machine appears to be sufficient in quantity to lower the temperature of the circulating atmosphere by one degree. If, as seems to be probable, six or seven of these machines can be employed at each working face, we may by this means lessen the heat by a corresponding number of degrees, and thus afford very considerable relief. The employment of compressed air, as a motive power, in substitution of horse traction, is also quite feasible, and may be expected to become quite general in very deep workings. As regards ventilation, the fan machines of the several constructions tried have already exhibited great superiority over the old method of ventilating by an upcast furnace shaft; and although the efficiency of the furnace system of ventilation is increased by depth, there is reason to believe that the fan will maintain its superiority to greater depths than are likely to be reached in mining.

THE BISSELL TENDER TRUCK.—One of these trucks, put on the "fast freight" engine *Elephant*, of the Boston and Albany railroad, in January, 1868, has been run some 45,000 miles without any expense for repairs. The forward wheels, over which is the center bearing spring peculiar to Mr. Bissell's improvement, are good for many thousand miles more of service, while the wheels of the rear truck, though carrying less weight per wheel, had to be renewed some three months since. This fact, coupled with its steadiness on the track; unexampled ease in passing through curves; saving of expense in first cost, and general simplicity of arrangement, makes this device a favorite with all master mechanics who have used or seen it. Locomotive drivers all unite in desiring it to be applied to their engines.

HYDRAULIC BUFFERS.

From a paper read by Col. H. CLERK, R. A., F. R. S., before the British Association, and entitled "Description of the Hydraulic Buffers and Experiments on the Flow of Liquids through Small Orifices at High Velocities."

In consequence of a suggestion made to me in October, 1867, by C. W. Siemens, Esq., C. E., F. R. S., to try the effect of water to check the recoil of heavy guns, I submitted to the Secretary of State for War a compressor or buffer on the above principle. It has been tried with guns varying in weight from only 150 lbs. to 25 tons, and in all cases the results have been most satisfactory. The amount of recoil can be regulated to a great nicety, and the motion is smooth and regular.

It consists of a wrought-iron cylinder closed at one end, the other end fitted with a cap and stuffing-box, through which a piston-rod passes. The length of the cylinder and piston-rod are regulated by the amount of recoil required, on the space within which it is necessary to bring the moving body to rest. The piston fits well into the cylinder, and is perforated with four small holes.

The ratio between the diameter of these holes and that of the cylinder is determined by the amount of work required to be performed in the water with which the cylinder is filled, enough air space being left to allow of the displacement of water by the length of piston rod due to the recoil. This air space also acts as an elastic buffer, and takes off the violence of the first impact of the piston on the water.

The cylinder is firmly attached to the platform on which the carriage recoils, and the end of the piston rod to the carriage itself, so that on the discharge of the gun the carriage drives the piston through the water with an initial velocity (V), while the water has to pass through the holes with an initial velocity (R V), R being the ratio between the area of the cylinder and that of the holes.

This buffer has not only been used with guns on shore up to 25 tons weight, but also at sea, with light guns of only $1\frac{1}{2}$ cwt., and 8 cwt. in boats, and lately with 9 in. guns of 12 tons on board H. M. S. Prince Albert, in all cases with equal success.

In place of water it has been recommended to use oil, as there is less chance of corrosion taking place if the cylinder is kept full for any lengthened period, and no danger of the fluid freezing in ordinary frost. The oil used for this purpose is Field's Rangoon oil, which does not become thick except in very cold weather, where Field's non-freezing oil may be used. A small portion of caustic soda in the water has been found to keep the cylinder perfectly clean and free from rust for many months.

The satisfactory manner in which this buffer has worked in checking the recoil of a gun of 25 tons weight, leads me to anticipate that it could be most usefully applied towards preventing or very sensibly diminishing the destructive effects of a railway collision, for as by means of this hydraulic buffer a force of impact varying from 12,000 foot-pounds up to 54,000 foot-pounds has been easily overcome in distances from 16 to 60 in., and inclinations ranging from $+10°$ to $-4°$, I see no reason why this principle should not be extended to overcome a force of, say, 1,500,000 foot-pounds in 60 in.

In checking the recoil of a gun, the velocity to be dealt with seldom exceeds 10 or 12 ft. per second, but in case of a railway collision it is very different, for we have then to deal with very high velocities.

It is therefore necessary to ascertain how the hydraulic buffer will act under these circumstances. For this purpose I have been carrying on a series of experiments on velocities up to 44 ft. per second, or 30 miles an hour, and now forward a short account of these for the information of the members of the British Association.

Two sets of experiments have been made, one with a cylinder 4 in. in diameter, the other with a cylinder 8 in. in diameter. With both the former the velocities tried were 10, 15, 20, and 25 ft.; the second with weights of 2,324, 1,162, and 581 lbs., and with ratios between the diameter of the cylinder and the holes in the piston of 15, 21, and 27.

With the latter the velocities were 10, 15, 20, 25, 30, 35, 40, and 44 ft. per second; the weights were 1,165, 2,324, and 4,648 lbs.; the ratios 15, 12, 9, 7, and 6. The velocities were obtained by drawing a truck (loaded to the proper weight) up an inclined plane of 47° to the proper height, and suddenly releasing it (a small deduction has to be made for friction). The truck ran down the slope, and, striking the end of the piston rod, drove it in till the resistance of the water overcame all the force of impact.

The cylinder with piston rod drawn out was fixed to the bottom of the inclined plane, about two trucks' length from the end of the slope, and was securely bedded in a block of wood, propped up behind to prevent its moving. Above the cylinder was fixed a light barrel, 6 ft. in length, made to rotate at the rate of one revolution per second, on which was fixed a sheet of drawing paper; to the end of the piston rod was fixed a pencil kept in contact with the rotating barrel by means of a light spiral spring, so that at each collision the piston rod transferred to the paper a curve, showing the time occupied in passing over every portion of the space through which it was driven.

From these curves a series of Tables have been formed showing the velocity of the piston rod for every 2 in. of the stroke. The diameter of the rotating barrel was 12 in., so that one second of time was represented by a space of 37.7 in. Another pencil was attached to the truck in a similar way to the one on the piston rod; thus two motions were determined, the one of the pistons through the water, the other of the truck when in contact with the piston rod.

A disc of Clarkson's material (a combination of cork and leather) was fixed to the end of the piston rod, and another to the front of the truck, where it came in contact with the piston rod in order to deaden the force of the blow. Two discs of india-rubber were fixed to the wood block in which the cylinder was bedded, against which the truck struck in those cases where the force was sufficient to drive the piston right home. The amount that these india-rubber discs were compressed was self-registered, and the value of such compression in foot-pounds having been previously ascertained, we are enabled to estimate the remaining force with which the truck struck the cylinder block. The same relative quantities of water and air were used in all the experiments.

In 4-in. cylinder	water......	380.6	cubic in.
	air........	97.8	"
Total capacity of cylinder		478.4	"
Diameter of piston rod		1.5	"
In 8-in. cylinder	water......	2,794	"
	air........	424	"
Total capacity of cylinder		3,218	"
Diameter of piston rod........		2.375	inches.
Ratio of thickness of piston to diameter of holes..........		$2\frac{1}{2}$ to 1	"

Different descriptions of fluids, such as oil, glycerine, and methylated spirits, were tried as well as water. With a perforated piston the resistance of the water is not uniform, being greatest at the commencement, or rather at that point where the air has received its maximum compression. It was, therefore, considered desirable to try the effect of uniform resistance, and Mr. Butler (Constructor R. C. D.) suggested a very simple mode of doing this. It consisted in fixing along the length of the cylinder four tapering rods, which passed through the holes in the piston; these holes were considerably enlarged, and the smallest end of the rod being towards the front, there was a large area for the water to pass through in the first instance, gradually diminishing in proportion to the decreasing velocity of the piston, thus keeping up an uniform velocity of flow through the holes.

In order to get the effect of an air buffer, for the sake of comparison, a solid piston fitting well in the cylinder was also tried. It would exceed the limits of this paper to give all the tables of velocities and plates of curves, but I think the accompanying diagrams will give an idea of the nature of the experiments.

In Table I are included the results of all the experiments, showing the total length of stroke and time occupied in each case with velocities up to $43\frac{1}{2}$ ft. per second.

In Table II, I have shown a comparison between the actual results obtained and those calculated by the following formula, based on the assumption that the work done on the water to produce a certain velocity is equal to that which has been expended in raising the water to the height from which it would have fallen to acquire the same velocity:

$$L=\frac{W e^2}{A w R^2}\log^2\left\{\frac{A w R^2 V^2}{2 g W \omega e^2}+1\right\}$$

L=length of stroke.
W=weight of truck.
A=area of piston.
R=ratio of area of piston to orifice.
V=velocity at impact.
ω=62.5 (weight of a cubic foot of water.)
w=coefficient of friction of piston-rod, &c.
e=coefficient of discharge.

The above formula applies when the action is on water alone, and the cylinder quite full; a correction therefore is necessary on account of the air space.

It appears, from experiment, that the air is compressed into about three-fourths of its original bulk before any material resistance is offered to the piston.

Some trials were also made with the 4-in. cylinder quite full of water and a solid piston, the water being driven out of the cylinder through a 1-in. hole at the end.

The ratio in this case was 16 to 1. The difference between the length of stroke in this case and with the usual air space of 97.8 cubic inches, equal to 7.7 in. in length of cylinder, was found to be about 6 in., allowing for the slight difference in the ratios 15 and 16. In the case of the 8-in. cylinder the air space amounts to 424 cubic inches. This divided by the area gives 8.5 in. in the length of the cylinder, three-fourths of which is 6.4 in. A correction, therefore, of 6.4 in. has to be added to the calculated length in the experiments with the 8-in. cylinder, and of 6 in. in the case of the 4-in. cylinder.

The coefficient of friction, w, of the truck and piston was found by experiment to be .05 in the 8-in. cylinder, and .046 in the 4-in. cylinder.

The value of the coefficient of discharge, e, has been assumed as .58 throughout, but it appears that this value is not constant for all velocities and all weights. I am, therefore, going to make some further experiments specially to determine this point, and also to ascertain the amount of irregularity caused by the compression of the cork discs.

With these exceptions, the formula appears to give results quite near enough for all practical purposes.

The Construction of Heavy Artillery.—The name of Mr. Lynall Thomas has for long past been associated with the development of the true principles of the science of artillery. Some ten years since, he started his theory of the nature of the action of gunpowder, which he calls the percussive theory. He has now, in a pamphlet of seventeen pages, developed this theory in a most skillful manner, and has laid down the true basis upon which heavy artillery should be constructed. In order to prepare our minds for the reception of his ideas, Mr. Thomas begins by sketching the theory as laid down by Robins and Hutton, and which was even by them considered faulty. Of course it must be borne in mind that those two students in this field of science labored principally with a view of ascertaining the effects of a discharge as far as the velocity of the shot and its curved path, etc., were concerned, and the errors of their theory were not brought forth in those startling colors which more recent experiments have imparted to them. They had no such great and costly guns to deal with as we have now; and the bursting of one of their 32-pounders was not so serious a matter to them as similar accidents, which are continually depriving us of the substantial results of immense labor and expense, are to us. It soon became evident, on the introduction of heavy rifled ordnance, that not only was something wanting to render the rules laid down in the old theory applicable, but that there was some radical and serious error. Large guns which had been constructed at a fabulous cost and were regarded as most perfect specimens of mechanical ingenuity, exhibited such symptoms of premature decline, on being tested by charges less than they were intended to carry, as to baffle the skill of the most experienced engineers. Some of these destructive engines bulged, and so became unfit for service; others, although preserving their external form, were found, after being used for a short time, to have contracted in some mysterious manner a steadily corroding disease, whilst others, again, in a still more alarming fashion, burst into fragments and disappeared with the charge that rent them.

The profession was utterly unable to account for these untoward mishaps. The elder members of the profession, no doubt, congratulated themselves on having been educated in a school in which the construction of such massive pieces was never contemplated, whilst the younger members escaped from the dilemma by asserting that gunpowder was not subject to the control of the laws that regulate the operation of physical or chemical forces. In fact, these irregularities were regarded as nothing more nor less than freaks of nature. It is from this painful state of uncertainty that Mr. Thomas promises to relieve us, and we have every reason to hope, from the suggestions offered in his pamphlet, that his promise will be performed. The word "percussive" conveys to us as much information as names and definitions generally do. In the first place, it is laid down that the whole charge is not inflamed at one and the same instant. This important fact will not be disputed, as it has been already recognized by nearly every writer on the subject. Mr. Thomas then proceeds to assert that that portion of the charge which has been converted into gas impinges with a terrific velocity upon the shot, and begins to expel it before the whole charge is completely consumed, or its force fully developed. This fact, no doubt, induced Mr. Thomas to adopt the phrase "percussive theory," for, as he subsequently says, "the whole time that elapses between the ignition of the charge and the expulsion of the shot from the pieces is scarcely sensible." So far the action of the portion of the charge initially inflamed is of an impulsive or percussive nature, generating, as it does, velocity in the shot in an indefinitely short period of time. After this we arrive at the gist of the whole theory. "Whilst the shot is traversing the initial space the rest of the charge is undergoing complete conversion into gas, and when such conversion has taken place the gas rushes forth in the direction of the axis of the bore." This volume of gas by means of its kinetic energy condenses a portion of itself in that space that has been just vacated by the shot.

Mr. Thomas then proceeds to narrate how he was induced by these considerations to make a series of experiments for the purpose of ascertaining the relation between the initial velocity of the shot, its own weight, and that of the powder employed. Four laws are stated as the results of his observations. By the aid of these laws he deduces expressions for the initial velocity, the tensional strain, and the corroding effect of the pressure. It is then shown how the weights of the powder and shot may be varied according to circumstances without altering the strain on the gun.

It must be confessed that there is something very plausible in this theory; the principles which it embodies are being daily recognized by those who have had experience in gunnery. We hope that our authorities will soon take the important subject into consideration. We shall ourselves hail with delight the establishment of a theory which promises to ensure the safety and perfection of those mighty instruments for the preservation of peace, and to relieve us from the fear of having such gigantic offsprings of labor and ingenuity cut off by any more erratic freaks on the part of nature.—*Mechanics' Magazine.*

MARINE ENGINE ECONOMY.—To that large branch of the mechanical engineering profession whose members are designers or constructors of marine engines, nothing, at the late Newcastle meeting, could have afforded more interest than the fine ships building at Leslie's (of Hebburn) for Lamport & Holt, and the remarkable engines, constructing by Robert Stephenson & Co., intended to push them 30,000 miles out and home between Liverpool and China. The ships—four in number, and intended for the tea trade—are each 315 ft. long, with proportionate beam and depth. The engines, designed by Mr. Alfred Holt, are unique. For each ship there is a compound engine, working upon a single crank—a 29 in. high pressure, and 66 in. low pressure cylinder, with 4 ft. stroke of pistons. The high pressure steam is taken from boilers worked at 75 lbs. per sq. in.—boilers 9 ft. in diameter, and made of West Cumberland hematite plates, $\frac{3}{4}$ in. thick, and double riveted on all seams. It need hardly be mentioned that these boilers are fed from their own condensed steam, the surface condensers being fitted with wood ferrules. There are two boilers in each ship, each boiler having two circular furnaces at each end, making eight furnaces in all for each vessel. Each furnace is 3 ft. 6 in. in diameter, and of proportionate length, the outlet from each furnace being through a short 18 in. flue communicating with a combustion chamber at the mid length of the boiler. From this combustion chamber 90 tubes, each 4 in. in diameter, and 8 ft. 2 in. long, return to each front or furnace end, making 180 tubes in each boiler, or 360 in all for the pair. The waste products of combustion are again led back, over the boiler, through a super-heater, to a chimney common to both double boilers, with their eight furnaces. The cylinders themselves, a top high pressure and a bottom low pressure, are enclosed in a wrought-iron steam-jacket 6 ft. or more in diameter. The details of these engines are cleverly designed, and the workmanship is all that a *connoisseur* would expect from the great house of Robert Stephenson & Co., who, by the way, ought, by this time, to be commissioned by the Admiralty.

It is asserted, upon the best authority, that ships of the class under notice, with Holt's engines, make their eleven knots an hour, month in and month out, and at a rate of consumption hardly rising to 2 lbs. of coal per indicated horse-power per hour.—*Engineering.*

PRODUCTION OF STEEL RAILS.—The rail mill of Messrs. John A. Griswold & Co., Troy, is now turning out 60 to 70 tons of steel rails per day. A part of the rails are rolled from hammered blooms, and a part from ingots bloomed and then reheated before being rolled into rails. Several rail ends from each charge of steel are tested by blows from a 5-ton hammer.

HYDRAULIC SWING BRIDGES.

THE ARMSTRONG SWING BRIDGE OVER THE OUSE.

By Sir William E. Armstrong.

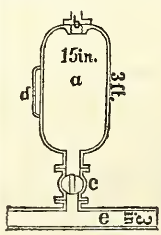
A paper read before the Institution of Mechanical Engineers at Newcastle.

The formation of the Hull and Doncaster section of the North-Eastern Railway necessitated the crossing of the river Ouse by an opening bridge, so as to admit the passage of the important traffic carried on in large sailing vessels. It was also necessary that that there should be not more than one pier in the navigable channel, with a clear opening of not less than 100 ft. on each side. The requisites of the railway and river traffic necessitated a construction that admitted of being opened and closed very rapidly. It was also necessary that the power applied should be capable of controlling with great accuracy the momentum of so ponderous a mass, and hydraulic power, being so eminently qualified for this purpose, was therefore selected as the agent. The instances in which hydraulic power had been previously applied to the opening and closing of movable bridges are very numerous, amounting to upwards of fifty examples. Most of these bridges have been erected for the passage of railway traffic, both on main lines and branches, and they may be divided into three classes. 1st. Swing bridges on which the bridge is lifted from its solid bearings by a central press previously to being turned by hydraulic pressure. 2d. Swing bridges on which the bridge rests upon a circle of two rollers, and is turned by water pressure without being lifted. 3d. Draw bridges on which the movable platform is drawn back and pushed forward in the line of the roadway by means of hydraulic machinery. In addition to the hydraulic bridges comprised in these three classes, there is one example of a bridge on the bascule plan being worked by hydraulic power. This is at Liverpool, over one of the dock entrances. The first hydraulic swing bridge was erected in 1852 over the river Severn, on the Gloucester and Dean Forest Railway, and the first hydraulic drawbridge was erected in 1853, over the river Tovey, on the South Wales Railway, near Carmathen. All the swing bridges which turn on a center pier, and span an opening on each side, have been made to turn on live rollers without being lifted; because, in bridges of that construction, neither extremity can have any steadying support in the act of turning, but in some instances a central press has been applied to relieve the rollers of part of the weight. Where single-leaf swing bridges are lifted by a central press, the deflection is taken off by letting down the bridge upon its solid bearing when closed; but in the case of drawbridges and swing bridges not lifted by a central press, hydraulic machinery is applied to lift the overhanging end or ends so as to take off the deflection after closing. The openings crossed by these various forms of bridges have varied from 30 to 100 ft. span. The heaviest bridge to which the central lifting arrangement has been applied is one over the Regent's Canal, near the London Docks, in which instance the weight lifted and turned amounts to 450 tons. In bridges with the central press, the head of the lifting ram fits into an inverted cup upon the bridge to allow of oscillating movement, and the bridge in swinging turns upon the water by carrying the ram 'round with it. The pressure of water employed in the central hydraulic press is about 800 lbs. per square inch, and in the largest of these bridges the diameter of the ram turning upon the water is 51 in. In most cases the bridges are in connection with a system of hydraulic pressure applied to cranes and other machines in the vicinity, the pressure being supplied in the usual manner by steam engines pumping into accumulators. But in some few instances, where there is not such a supply of power at hand, the pressure is supplied by hand pumps charging the accumulator, and thus storing up the power ready for application whenever required. At the Ouse Bridge there was no supply of hydraulic power at hand, and in that instance the total power required was too large to be supplied by hand labor. It was further necessary, on account of the position of the swing bridge, either to convey the power to the center pier by a pipe under the bed of the river, or to produce it upon the pier by placing a steam engine within the pier itself, and the latter plan was adopted.

The total length of the bridge, fixed and movable, is 830 ft. The fixed portions consist of five spans of 116 ft., from center to center of piers. The bridge being for a double line of railway, each span is composed of three wrought-iron girders of the bow-string form, the center girder having a larger section to adapt it for its greater load. These girders have single webs, and are 9 ft. deep in the center. The total width of the bridge, from outside to outside, is 31 ft. Each of the piers for the fixed spans consists of three cast-iron cylinders, of 7 ft. diameter and about 90 ft. in length. The depth from the under side of the bridge to the bed of the channel, in the deepest part, is about 61 ft. The headway beneath the bridge is 14 ft. 6 in. from high water datum and 30 ft. 6 in. from low water. The swinging portion of the bridge consists of three main wrought-iron girders, 250 ft. length and 16 ft. 6 in. deep at the center, diminishing to 4 ft. deep at the ends. The center girder is of larger sectional area than the side girders, and, instead of being a single web, is a box girder 2 ft. 6 in. in width, with web plates $\frac{7}{16}$th to $\frac{5}{16}$th in. in thickness, and the top and bottom boom contains about 132 sq. in. of section. The roadway is carried upon transverse wrought-iron girders resting upon the bottom flanges of the main girders. In the center of the bridge the main girders are stayed by three transverse wrought-iron frames securely fixing them together; and over the top of these frames a floor is laid, from which the bridge man controls the movements of the bridge. An annular box girder, 32 ft. mean diameter, is situated below the center of the bridge, and forms the cap of the center pier; this girder is 3 ft. 2 in. in depth, 3 ft. in width, and rests upon the top of six cast-iron columns, each 7 ft. diameter, which are arranged in a circle, and form the center pier of the bridge. Each of these columns has a total length of 90 ft., being sunk about 29 ft. deep in the bed of the river. A center column, 7 ft. in diameter, is securely braced to the other columns by a set of cast-iron stays, which support the floor of the engine-room. This center column contains the accumulator, and forms the center pivot for the rotation of the bridge. The weight of the swing bridge is 670 tons. There is no central lifting-press, and the entire weight rests upon a circle of conical live rollers. These are 26 in number, 3 ft. diameter and 14 in. width of tread, and are made of cast-iron, hooped with steel, and they run between two circular roller paths 32 ft. diameter. These roller paths are 15 in., and are made of cast-iron, faced with steel; the axles of the rollers are horizontal, and the two roller paths are turned to the same bevel. The turning motion is communicated to the bridge by means of a circular cast-iron rack $12\frac{1}{2}$ in. wide on the face, and $6\frac{1}{2}$ in. pitch. It is shrouded to the pitch line, and is bolted to the outer circumference of the upper roller path. It gears with a vertical bevel wheel, which is carried by a steel center pin, supported on the lower roller path. This is driven by a pinion connected by intermediate gearing with the hydraulic engine. There are two of these engines, duplicates of one another, either of which is sufficient for turning the bridge. The force required to turn the bridge is equal to about ten tons applied at the radius of the roller path. Each hydraulic engine is a three-cylinder oscillating engine, with simple rams $4\frac{1}{4}$ in. diameter and 18 in. stroke. These engines work at 40 revolutions per minute, with a pressure of water of 700 lbs. per inch, and are estimated at 40-horse power each. The steam engines for supplying the water pressure are also in duplicate, and are double cylinder engines, driving three throw pumps 2.8 in. diameter and 5 in. stroke, which deliver into the accumulator. The diameter of the steam cylinders is 8 in., and the stroke of the piston is 10 in., each engine being 12-horse power, The accumulator consists of $16\frac{1}{2}$ in. ram, with a 17 ft. stroke, and is loaded with a weight of 67 tons, the weight being composed of cast-iron segments suspended from a crosshead and working down in the cylindrical casing formed by the center cylinder. For the purpose of obtaining a perfectly solid roadway when the bridge is in position for the passage of trains, and also for securing the perfect continuity of the line of rails, the following apparatus is applied: Each extremity of the bridge is lifted by a horizontal hydraulic press acting upon levers, forming a toggle joint, the piers having two rams acting in opposite directions upon two toggle joint levers, which act one upon each side of the end of the bridge, and they are connected by a horizontal bar, which is confined by a stud sliding in a vertical guide, so as to ensure parallel action of the two toggle joint levers, and producing exactly parallel lifting of the two sides of the bridge. Three resting blocks, one under each girder, are pushed home when the end of the bridge is lifted by means of two separate hydraulic cylinders, and the bridge is then let down upon the resting blocks by the withdrawal of the toggle joint levers, and the bridge ends are then perfectly safe for trains to pass over. The hydraulic cylinders for this fixing gear at the two ends of the bridge are worked by the bridgeman from the center platform by means of two levers, and for the purpose of enabling him to regulate the stopping of the motion of the bridge at the right place an indicator is provided, consisting of a dial upon a pedestal. This dial has two pointers, which are actuated by the motion of the bridge. One of these two pointers makes two revolutions, and the other 42 revolutions for one complete rotation of the bridge. These pointers are similar to the hour and minute hands of a watch, the slower pointer being analogous to the hour hand, and the quicker one to the minute hand. The bridge has no stop to its movement, and would swing clear past its right position if the turning power were continued; but the bridgeman, being guided by the indicator, knows when to stop and reverse the hydraulic engines for the purpose of stopping the bridge at its right place. When this is done, a strong bolt, 3 in. thick, in each end of the bridge, pressed outwards by a spiral spring, is shot into a corresponding notch in the fixed girder work, so as to lock the bridge; and when the bridge is required to be opened, these bolts are withdrawn by a wire cord leading to the platform on which the bridgeman is stationed. As the accumulator is stationary, and the fixing gear at the ends of the bridge travels with the bridge, the communication of water power is made by a copper pipe passing up in the axis of the bridge through the middle of the center girder, having a swivel joint at the lower end. Also, as the hand gear for the bridgeman rotates with the bridge, while the hydraulic turning engines are stationary, the communication for working the valves is made by a copper rod passing down through the center of the above pressure pipe in the axis of the bridge. This rod is connected by levers direct with regulating valves of the hydraulic engines, and the engines are reversed in either direction by the action of a small hydraulic cylinder, which is governed by the movement of a three-port valve, actuated by this rod from the bridgeman's platform. The cylinders for working the fixing gear at the ends of the bridge are worked by valves placed upon the center platform in reach of the bridgeman, the pipes between the valves and the cylinders passing along the side of the roadway of the bridge. The time required for opening or closing the bridge, including the locking of the links, is only half a minute, the average speed of motion at the extremities of the bridge being $6\frac{1}{2}$ ft. per second. For the purpose of ensuring safety in the working of the railway line over the bridge, a system of self-acting signals is arranged, that is actuated by the fixing gear at the two ends of the bridge, and a signal of 'all right' is shown by a single semaphore and lamp on the fixed part at each end; but this cannot be shown until each one of the resting blocks and bolts is secured in its proper place.

A Syphon for Draining a Tunnel.—The tunnel through the Blue Ridge, in Virginia, is 4,273 ft. long, and 700 ft. below the top of the mountain; on this account it was thought expedient to construct without shafts. This tunnel slopes from west to east, at the rate of 70 ft. to the mile, so that on the west side, the water, which proved very abundant and troublesome, had to be removed by artificial means. For some distance at the entrance, I determined to introduce a syphon of unusual length, which proved a difficult and, at the same time, interesting experiment.

The whole length of the syphon is 1,792 ft., viz: 563 ft. inside of the tunnel, and 1,229 ft. outside. The level of the water inside is upwards of nine feet below the summit, and the fall outside $29\frac{1}{4}$ ft., so that the head is a fraction over 20 ft. Iron faucet pipes of three in. interior diameter were adopted. It was feared that larger ones would carry along too much air; and that the syphon would have to be fed too often at the summit, an apprehension which the results observed seem to justify. A common faucet cock is placed at each end, to close the syphon when it becomes necessary to fill it again with water; and at the summit a large air vessel is provided to collect the air disengaged from the water, with a suitable opening at top, to let the air out and replace it with water; this opening being closed by a cap tightly screwed down. At the bottom of the air vessel, there is besides a large cock, which is closed while the syphon is being fed through the top opening, so as not to interrupt the running of the syphon during the operation.



The annexed diagram represents the air-vessel *a*; *b* is the cap; *c* the cut-off cock; *e* the main pipe or syphon; *d* is a glass tube for observing the level of the water. This, however, being often broken, was dispensed with at last; the level of the water being easily ascertained by knocking against the air-vessel.

Things being now disposed as described, it might be supposed that the discharge would have gone on uninterruptedly, requiring only a careful attention to replenish occasionally with water the air vessel; but such was not the case; at first the joints had been made tight by packing with oakum and then thickly pitched over. The syphon was filled with water through the air-vessel, which being then closed and the ends open, the water began to flow; but this did not continue for more than five or ten minutes, when the air-vessel was found empty of water, and had to be replenished at these short intervals; moreover, notwithstanding this tedious repetition of feeding the syphon, it would ultimately run dry in about two hours.

This was a truly discouraging circumstance; we ascribed it to the fact that, there being upwards of 200 joints, air was introduced in small bubbles through the oakum packing by the external pressure at every joint, and that it accumulated rapidly all along, especially in the longer arm of the syphon, which soon became too light. Accordingly, we decided not to abandon the enterprise, but to caulk the joints with lead in the usual way, which was not done before for motives of economy, and because, it being only a temporary fixture, it would have been more easily taken apart.

This operation was not yet entirely successful, though the caulking was made so hard that many of the bells broke in packing, without making the joints perfectly impermeable. Then a cement was made of equal parts of white lead and red lead mixed to the consistency of soft putty, with equal quantities of Japan varnish and boiled linseed oil. This cement, carefully coated over the joints, made them at last perfectly tight. The syphon, thus improved, runs now regularly. Still the air-vessel must be replenished with water every two hours, which is done by a pipe leading from a spring, and, moreover, every six hours the ends must be closed, and the whole syphon filled in anew with water; otherwise it would run dry.* It is probable that, owing to its being so long, and consequently so level, bubbles of air travel along very slowly and increase in size gradually; possibly some air may find its way under external pressure through the iron itself.

* Would not this be remedied by making the air-vessel *self-acting* like the air valves sometimes used on water mains?—*Note by J. C. Trautwine.*

A curious circumstance took place in the beginning: the tunnel having progressed much beyond the well of the syphon, and the water considerably increased, a horse power with chain pumps was constructed at the further end to pump up the water into troughs, by which it is led to the syphon well. Here, the syphon being insufficient for this accession of water, another horse power was introduced to pump up water out of the same well. As soon, however, as the chain pumps began to revolve in the well, the syphon suddenly stopped and we were obliged to dig a separate well for it; since which time both have worked well.

The syphon, by actual measurement, when just replenished, discharges $43\frac{1}{2}$ gallons per minute, whereas, all known formulæ give between 54 and 60 gallons, and furthermore, in "Weale's Engineers' and Contractors' Companion," occurs this conflicting remark, taken from R. A. Peacocke's work:

"By Dr. Young's formula (considered by him the best)—

A 5-inch	pipe	would	be used	where a	$3\frac{1}{2}$	would suffice.
7	"	"	"	"	5	"
10	"	"	"	"	7	"
14	"	"	"	"	10	"

and then he goes on to show the useless expenditure resulting from pipes too large being used in obedience to these formulæ. But here in this extraordinary long syphon, his opinion is not sustained, and we find, on the contrary, the discharge is less than the formulæ give; and that neither they nor Mr. Peacocke's rules are applicable to this case.

The syphon I have described is, I believe, the longest ever attempted to be used, and on this account the results and anomalies it presents are somewhat interesting. It certainly has rendered considerable service in the Blue Ridge Tunnel; with no other current expense than the employment of a man to attend to the air-vessel.—*Col. C. Crozet in Journal Franklin Institute.*

TESTING RAILS AND AXLES.—A suitable movable anvil, to be placed temporarily upon the flat anvil of a heavy steam-hammer, makes a convenient testing machine. It has been proved by experiment that a 5-ton hammer falling 20 inches upon a rail having one foot bearings, is about equivalent to a 1-ton weight falling ten feet upon a rail having three feet bearings.

ON THE THERMAL ENERGY OF MOLECULAR VORTICES.

Abstract of a paper before the Royal Society of Edinburgh, by W. J. MACQUORN RANKINE, F. R. S., &c.

In a previous paper, presented to the Royal Society of Edinburgh in December, 1849, and read on the 5th of February, 1850 (Trans. vol. xx.), the author deduced the principles of thermodynamics, and various properties of elastic fluids, from the hypothesis of molecular vortices, under certain special suppositions as to the figure and arrangement of the vortices, and as to the properties of the matter which moves in them. In subsequent papers he showed how the hypothesis might be simplified by dispensing with some of the special suppositions. In the present paper he makes further progress in the same direction, and shows how the general equation of thermodynamics, and other propositions, are deduced from the hypothesis of molecular vortices, when freed from all special suppositions as to the figure and arrangement of the vortices, and the properties of the matter that moves in them, and reduced simply to the following form: *that thermometric heat consists in a motion of the particles of bodies in circulating streams, with a velocity either constant or fluctuating periodically.* This, of course, implies that the forces acting amongst those particles, are capable of transmitting that motion.

The principal conclusions arrived at are the following:

1. In a substance in which the action of the vortices is isotropic, the intensity of the centrifugal pressure per unit of area, is *two-thirds* of the energy due to the steady circulation in an unit of volume. The centrifugal pressure is the pressure exerted by the substance in the perfectly gaseous state.

2.* If there be substances in which the action of the vortices is not isotropic, then in such substances the proportion already stated applies to the mean of the intensities of the centrifugal pressures in any three orthogonal directions.

3.* The proportion which the whole energy of the vortices, including that of the periodic disturbances, bears to the energy of the steady circulation alone, may be constant or variable.

4. Absolute temperature is proportioned to the energy of the steady circulation in unity of mass, and to the specific volume in the perfectly gaseous state.

5. In substances which are nearly in the perfectly gaseous state, experiment shows the proportion in which the whole energy exceeds that of the steady circulation, to be sensibly constant; and its value may be found by computing in what proportion the dynamical value of the specific heat at constant volume exceeds once and a half the quotient found by dividing the product of the pressure and volume by the absolute temperature. *The following are examples:—air, 1.634; nitrogen, 1.630; oxygen, 1.667; hydrogen, 1.614; steam-gas, 2.242.

6. The known general equation of thermodynamics is deduced from the hypothesis of molecular vortices, *freed from the special suppositions made in the paper of 1849-50.

The new conclusions obtained in the present paper are marked *. Those not so marked were arrived at in the paper of 1849-50.

The general equation of thermodynamics is here stated for convenience; let dQ be the thermal energy which must be given to unity of mass of a given substance, in order to produce a given indefinitely small change in its temperature and dimensions: then—

$$dQ = \tau \; d \cdot \phi;$$

in which τ is the absolute temperature, and ϕ the thermodynamic function. The value of that function is—

$$\phi = Jc \text{ hyplog } \tau + \chi(\tau) + \frac{dU}{d\tau};$$

Jc being the dynamical value of the real specific heat; U, the potential energy of the elasticity of the body at constant temperature; and $\chi(\tau)$, a function of the absolute temperature, which is null or inappreciable in a substance capable, at that temperature, of approximating indefinitely to the perfectly gaseous state, and is included in the formula, in order to provide for the possibility suggested by Clausius, that there may be substances which have not that property at all temperatures.

THE CONNECTICUT WESTERN RAILROAD, a link in the Boston, Hartford and Erie, now building, will undoubtedly pay as a trunk line, but its chief value to the public, and ultimately to shareholders, will be the facilities it will afford for bringing cheap coal to the many manufacturing villages of Connecticut, and for carrying the excellent iron ores of the Salisbury and adjacent regions to the Hudson river, there to be smelted with anthracite coal.

AVELING & PORTER'S TRACTION ENGINES.

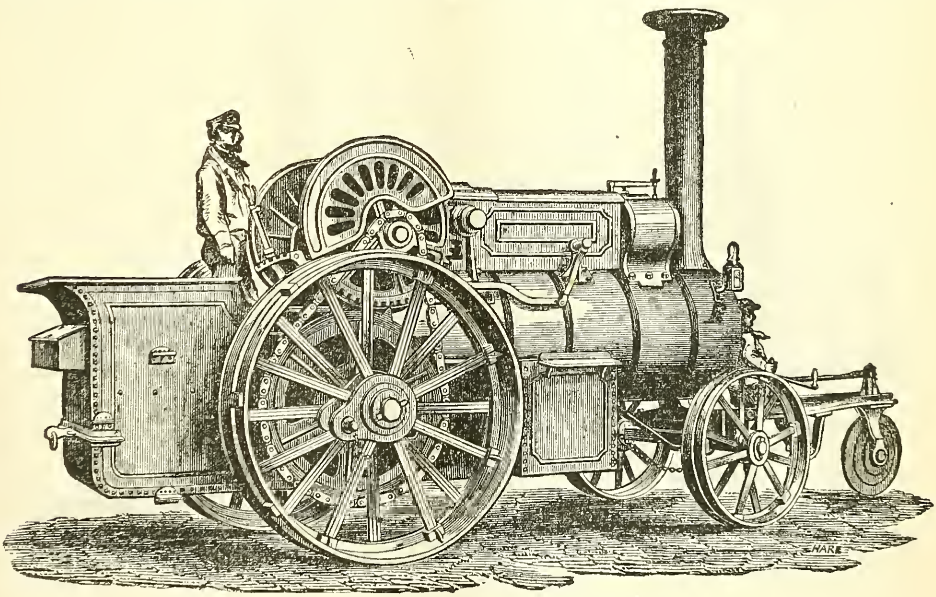
AGRICULTURAL LOCOMOTIVES AND TRAMWAY ENGINES.

The subject of Traction engines as locomotives for ordinary roads and for agricultural and other purposes, is attracting a large amount of attention in this country, but certainly not more than its vast importance entitles it to. In the London Exhibition of 1851, there was not one Traction engine, and it was the general belief that none could be contrived to answer any commercial purpose. In the London Exhibition of 1862, nine of these engines were exhibited. At the Royal Agricultural Society's meeting at Canterbury in 1860, Mr. Aveling, of Rochester, exhibited a self-propelling engine, but it was regarded with indifference by the officers of the society, and was catalogued with the "miscellaneous" articles.

Since that time, however, the importance and advantages of self-propelling engines over the ordinary "Portable engines," which have to be conveyed from place to place by horse-power, or otherwise dragged heavily along by a vast expenditure of manual labor, is an admitted fact, and not only are these Traction engines employed for agricultural purposes, but they can be seen in successful operation in England and many other parts of the world—in the timber yard, at the coal-field, the copper mine and the stone quarry, where they are doing the work of horses at less than half the cost.

The illustrations accompanying this article are perspective views of road locomotives and tramway engines as manufactured by Messrs. Aveling & Porter, of Rochester, England, and 43 Exchange Place, New York, who are amongst the most successful English makers of this description of engine.

Aveling & Porter's Patent Road Locomotive engine is arranged with double gearing to travel at two speeds, viz: $2\frac{1}{2}$ miles and 5 miles an hour. The working parts are housed in from the influence of dust and weather. This engine has one cylinder placed on the forward part of the boiler and surrounded by a steam-jacket, at the top of which is placed the throttle-valve. Priming in ascending steep inclines is thereby prevented, and the use of steam-pipes, either inside or outside the boiler, is avoided. Engines with single cylinders and reversing gear when connected to the driving axle by means of Aveling's patent chain gear, have proved themselves to be thoroughly efficient, more powerful, less complicated, and in many respects better adapted for general traction purposes than engines with double cylinders. The driving-wheels are 6 ft. 6 in. diameter, and 18 in. wide, and have spaces in the face in order to



Aveling & Porter's Patent Road Locomotive or Traction Engine.

fix on angle-iron paddles when passing over soft ground. Small castings slide into these spaces when the angle irons are not in use. Either of the driving-wheels can be rotated at pleasure, which is a great advantage in turning sharp curves. The tanks carry water and fuel for a run of from six to ten miles, according to the speed. A powerful friction-break is connected with the driving axle, and the patent arrangement for steering the engine is perfect in its action.

A most elaborate series of experiments have been lately made with one of Aveling & Porter's road traction engines, "La Ville de Senlis," at Beaurain, France. The experiments were conducted by M. Tresca, Engineer, Sub-director of the Conservatoire Impérial des Arts-et-Métiers, Paris, and approved by the Director-General, Moran. The experiments moreover were made in concert with Professor Fleeming Jenkin, F. R. S., London, whose presence gives to the results arrived at, a character of security that increases their importance.

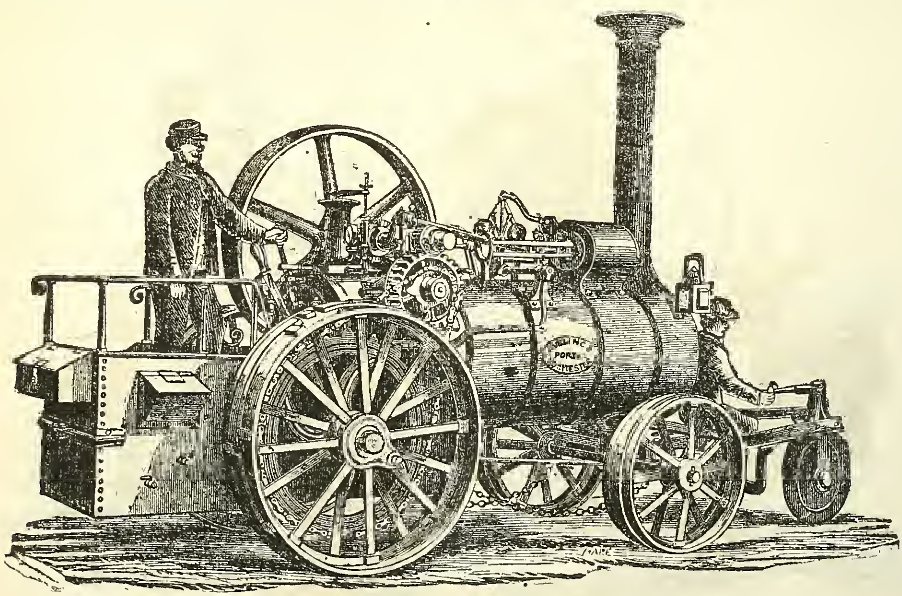
Soon after the Paris Exposition of 1867, a number of experiments having for their purpose the testing of the tractive power of Aveling's engine, were made with the engine "Pioneer," and these have been lately supplemented by more detailed and searching tests applied to the engine "La Ville de Senlis," manufactured by the same firm. The report, which is a very lengthy and carefully compiled paper, concludes as follows:

"To sum up. The engine (La Ville de Senlis) drew in a regular manner, upon a good road slightly undulating, a total load of 60,000 kilog. (59 tons). The co-efficient of traction may be approximately estimated at $\frac{1}{40}$, which would bring the mean strain to nearly 2,000 kilog. ($39\frac{1}{2}$ cwt.) taking into account the weight of the locomotive.

"This mean effort, developed at a speed of 1.108 m. (3.54 feet) per second, brings the valuation of effective work to 2,160 kil. met. (15,623 foot-pounds) per second, or to 28 chevaux vapeur (27.61 horse-power). This figure will appear high if it be compared with the consumption of fuel, which was 184 kilogrammes, (3 c. 2 q. 13 lbs.) in three hours and three minutes, say 60 kilog. (132.25 lbs.), per hour of actual traveling. This consumption represents only 2 kilogrammes (4.40 lbs.) of coal per horse-power and per hour.

"The corresponding consumption of water is not less than 600.46 liters (132.22 gallons) per hour of actual traveling. With the present tenders, which can hold 1,800 liters (396 gallons) of water, it is necessary to replenish them every 10 or 12 kilometers ($6\frac{1}{2}$ to $7\frac{1}{2}$ miles).

"The co-efficient of adherence may be estimated on the road gone over at .3 of the adherent weight.



Aveling & Porter's Agricultural Locomotive.

"The adherence resulting therefrom was only necessary for the working of the engine up inclines of .030 to .033 (1 in 33 to 1 in 30) and at starting.

"The load of 81,253 kilogrammes ($79\frac{1}{2}\frac{9}{0}$ tons) which the engine drew on level ground is not the limit of what it can draw under these conditions.

"The speed of four kilometers (2.48 miles) per hour appears suitable for fraffic of this nature, and renders the manœuvers so easy that the train is well managed by a superintendent, an engine driver, and an assistant solely employed to guide the steering wheel in front.

"Done by the Engineer, Sub-Director of the Conservatoire Impérial des Arts-et-Métiers.

"PARIS, 15*th January*, 1868.

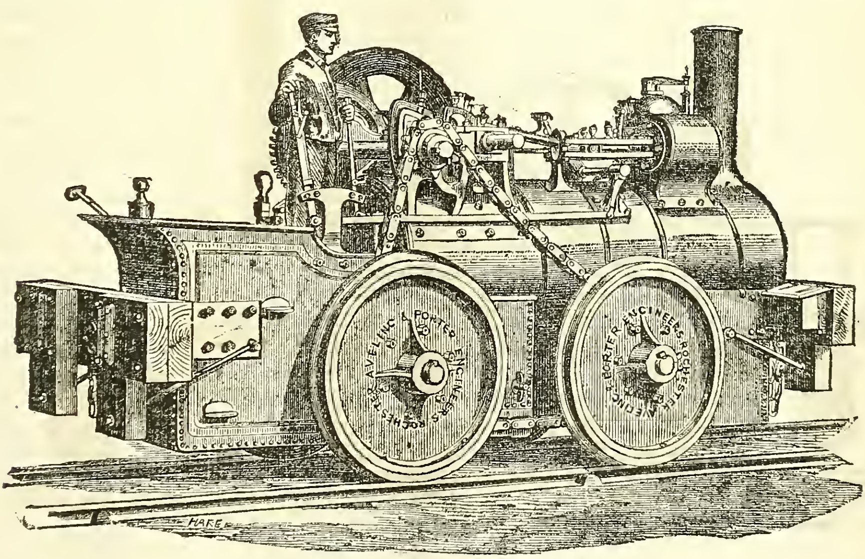
"Approved—The Director.

"GENERAL MORAN."

It is upon the general principles adopted in the manufacture of Aveling & Porter's road traction engine, that their agricultural locomotive has been designed. The second illustration gives a view of this machine, which is especially adapted for steam cultivation, thrashing, sawing, pumping, and removing agricultural produce. The boiler is unusually large; it is clothed entirely with hair felt, lagged and covered over with sheet-iron, and proved to a pressure of 200 lbs. to the square inch. Want of heating surface, and the use of steam pipes inside the boiler, causing loss from leakage and waste in reheating the exhaust steam on its passage to the atmosphere, are serious faults common in agricultural engines. In this engine the cylinder is placed on the forward part of the boiler, surrounded by a steam-jacket, and with arrangements otherwise similar to Aveling's road locomotive. The driving wheels are 5 feet 6 inches diameter, and 16 inches wide. The engine is capable of taking a load of from 10 to 15 tons over ordinary roads. There are 400 of these engines in use in England and many countries of the European continent, and the testimony of the best and most competent judges affirms the superiority and economy of the agricultural locomotive over all descriptions of engines used for farm purposes. The simple "Portable engine," without any capacity for propelling itself, is but a small "half measure" towards economy, and the difference in the cost of a locomotive and an engine which necessitates the expenditure of much time and expense for its removal is so trifling when compared with the advantages gained by the newer methods, that there is little doubt of the ultimate adoption in this country of a plan that has proved so entirely successful abroad. The prize medals of the International Exhibition, London, 1862, and the Universal Exhibition, Paris, 1867, were awarded to this engine.

The third illustration exhibits a locomo-



Aveling & Porter's Patent Tramway Engine.

tive so constructed as to be worked upon an ordinary tramway, and may be described as a traction engine placed upon railway wheels, these wheels being coupled by the pitch-chain, which is employed to communicate the motion to them. These engines are made from 4 to 30 horse-power. From the crank-shaft the motion is communicated by spur gearing to a countershaft, carrying at its end the wheel for the pitch-chain, the bearings of this shaft being placed in curved slots formed in the supporting brackets, so that the shaft can be raised and the chain tightened when necessary. The crank-shaft carries a fly-wheel, and the engine is fitted with Aveling's usual link-motion reversing gear. The pitch-chain extends from the countershaft around the chain wheels, fixed one inside each of the carrying wheels, and the chain thus couples the wheels together, as well as communicates the motion of the countershaft to them. The carrying wheels are 4 ft. diameter, and are placed at a distance of 5 ft. 3 in. apart from center to center, the leading axle passing under the barrel of the boiler, and the trailing one being placed behind the fire-box casing. The wheels are of cast-iron, and the total weight of the engine (a 10-horse power) 9 tons. These engines have the same advantages as portable and stationary engines for pumping, sawing, and driving fixed machinery; they are capable of taking heavy loads at the rate of six miles per hour, and at a cost of three farthings per ton per mile. They are in use in Her Majesty's dockyards at Chatham, Portsmouth and Davenport, and in many mines, quarries, brick-fields and other large works in England and other European countries.

In all parts of the United Kingdom are to be found these tramway engines; and horse-power, which was formerly employed for working in mines and quarries, has, in a great number of cases, been replaced by locomotives, and the cost of traction has thereby been materially reduced.

Altogether these engines have given abundant proof of being well adapted for use in quarries and similar places where heavy loads have to be moved at slow speeds, and in such situations it appears that they will do the work at about half the cost incurred by the employment of horse-power. W.

THE BAD COAL BURNING on most of our locomotives is a waste of money, a nuisance to passengers, and a disgrace to managers.

THE SPIRIT-LEVEL.

By JOHN PHILLIPS.

From "The Builder."

Its Invention.—He who first filled a glass bottle with a liquid, leaving a small quantity of air therein to form a bubble, then corked the bottle and laid it flat on one side, with the bubble floating against the upper part, was the unconscious inventor of the spirit-level, which is a very simple instrument in appearance, but of the utmost value, when properly made, to the astronomer, the engineer, and the builder; for when the bottle is placed horizontally, the bubble always mounts to, and rests at, its most elevated point; and the tangent to that point, when the middle or apex-point of the bubble coincides therewith, is a horizontal line; that is, a line at right angles, or perpendicular to the direction of gravity or the plumb-line passing through that point.

This was first perceived and applied, so far as is known, in France in 1666, by Melchisédec Thévenot, who was a great amateur of science, and a writer of books of voyages and travels. In this respect he enriched the literature of France as much as Hakluyt enriched that of England half a century earlier. It was at Thévenot's house that the learned men who founded the Academy of Sciences at Paris used to assemble; and it was at one of their meetings that he propounded the spirit-level.

A description of the instrument, accompanied with figures, was first published in the "Journal des Savants," Paris, November 15th, 1666, under this title: "Machine nouvelle pour la conduite des eaux, pour les bâtiments, pour la navigation, et pour la plupart des autres arts." The instrument is there called an *air-level;* and is described as a glass tube, hermetically sealed at both ends, containing spirits of wine, which do not freeze, and a small quantity of air forming a bubble. It is stated that the instrument is capable of giving, with much exactness, the direction of the horizon, the perpendicular to the horizon, and vertical angles; and that it is easier to make, more convenient to use, and indicates a level line more readily and accurately than any other instrument. One figure represents the tube charged with liquid, and an air-bubble; a second shows it fitted, under the center part, with a spindle dropping into a socket fixed on a staff so as to turn in any direction, and with sights on the ends for leveling to long distances; a third represents it fixed to a square, and a fourth to a short flat bar of wood, as levels for workmen; and a fifth shows it fixed to a quadrant for navigation.

In this first publication the inventor is not named. But in a small work, called "Recueil des Voyages de M. Thévenot," Paris, 1681, there is a description of the instrument by Thévenot, preceded by a statement that he invented it fifteen years before that time; and that he then gave a description of it to the public. This agrees with the description in the "Journal des Savants," referred to above, which no doubt was written by Thévenot himself. He also states that soon after its invention an account of it was sent to the Royal Society of London. The celebrated Dr. Hooke was then a constant attendant at the meetings of this body. By this means he became acquainted with it; and seeing that it would be of the greatest advantage to astronomy, to navigation, to engineering, and to building, he had some excellent tubes prepared, and applied them to various instruments; and he subsequently produced the spherical spirit-level. From this circumstance the invention of the spirit-level, now in common use, has been ascribed to Hooke, but it is undoubtedly due to Thévenot. Much merit is due, however, to Hooke for aiding to perfect it, and to apply it to science. He was the best practical mechanician of his time, as is evidenced by his numerous valuable inventions. He, as well as Wren, whose name is displayed in the most prominent of red-letters on the fame-roll of British architects, were contemporary with Newton; and both Hooke and Wren were within an ace of seeing and propounding the principle of universal gravitation at the moment when the great intellect of Newton had grasped and mastered it,—dispelling forever the mist that had obscured it.

As, however, the instrument was new, and there were difficulties in constructing it with precision, nearly a century elapsed before those difficulties were removed, and it obtained the preference it merited over the water-levels and plumb-levels then in use, as well as over those that were invented during the interval, most of which are now almost forgotten. It was first practically employed in this country, in 1756, by Smeaton, for leveling the foundation and courses of stone of the noble lighthouse which he designed and erected on the Eddystone. Thévenot's simple glass tube is now applied to nearly all the instruments used in leveling, and it is *the* level *par excellence.*

Its Construction.—The spirit-level, as ordinarily constructed, consists of a short cylindrical glass tube, whose interior surface is, or should be, ground to a slight regular curvature lengthways, and then polished. The curvature, which is much exaggerated in the figure, is almost imperceptible in the tube, the radius being from 300 ft. to 600 ft. The tube is nearly filled with a very limpid liquid, leaving a small space occupied by an air-bubble. The open ends are then hermetically sealed by melting the glass around them with the blow-pipe.

Alcohol or sulphuric ether, whose specific gravities are respectively .792 and .715, water being 1.000, are preferred for charging the tube, because these liquids are much lighter, possess the property of fluidity in a higher degree, and are more sensitive than any others. Moreover, intense frost does not affect their fluidity—no observed degree of natural or artificial cold having ever frozen them; and they also have the property of wetting the glass more readily and completely than other liquids, owing to the greater capillary affinity subsisting between them and the glass.

If the tube's curvature were the same as the earth's curvature, the upper line or surface of the liquid would be truly level, and therefore no part of it would have a tendency to fall, or seek a lower position; nor would the bubble, which is considerably lighter than the liquid, have a tendency to rise or seek a higher one, but would remain uninfluenced at any part, because the action of gravity upon the surface of the liquid would be everywhere precisely equal. It is essential, therefore, that the tube should be made not only of equal bore, or perfectly cylindrical throughout, but with a uniform and sensibly convex curvature, lengthways, in order that the middle or apex-point of the bubble may rise to, and rest at, the middle or apex-point of the arc.

As, then, the bubble moves in an arc of a circle convex upwards, it may be regarded as a *plummet of air*, analogous to a plummet of metal or a pendulum swinging in the arc of a circle convex downwards; and the center of gravity of the bubble is brought to rest, by the earth's attraction, in the vertical line passing through the center of the circle in the arc of which the bubble moves, the same as the center of gravity of the plummet or the pendulum is brought to rest, also by the earth's attraction, in the vertical line passing through the center of the circle in the arc of which the plummet or the pendulum swings, or through the point from which they are suspended. When, therefore, the apex-point of the bubble coincides with the apex, or zero-point, as it is called, of the tube, which is marked thereon, or the ends of the bubble mark equal distances therefrom, the instrument is in adjustment—that is, the tangent to the tube at the zero-point is horizontal, or at right angles to the vertical passing through that point.

Two symmetrically divided scales are usually engraved across the top surface of the tube—one on each side of the zero-point, or one from each end of the bubble when its apex-point is identical with the zero-point; so that when the bubble marks equal divisions on the scales, the tangent to the arc at the zero-point, as also a visual ray, a straight edge, or a line parallel thereto, is horizontal. When, on the contrary, one end of the tube is raised above the other, the bubble runs from the zero-point towards the elevated end, and the tangent to that point, or the visual ray, the straight edge, or the line parallel thereto, inclines upwards in one direction, and downwards in the other, from exact horizontality, while the tangent to the arc at the apex-point of the bubble, wherever situated, remains horizontal.

When, therefore, the radius of curvature of the tube is known, the scales across the tube are capable of measuring vertical angles with the same accuracy as a sector, whose radius is equal to the radius of the tube's curvature. Thus, when the apex-point of the bubble deviates from the zero-point of the tube, the value in seconds of the angle contained between the horizontal tangent to the bubble's apex-point, and the tangent to the tube's zero-point is

$$206265'' \times \frac{\text{deviation of bubble.}}{\text{rad. of curv. of tube.}}$$

For example, let the bubble's deviation from the zero-point be three divisions of the scale, or $\frac{3}{10}$ of an inch, and let the tube's radius of curvature be 300 ft.; then we have $206265'' \times \frac{3}{300} = 206265'' \times .01 = 2062''.65 = 34'\ 22''.65$, the value of the angle from horizontality.

The radius of curvature of the tube may be found by the formula

$$R = \frac{d}{h} D;$$

where R is the radius, d the deviation of the bubble, h the height traversed on a distant staff by the run of the tangent from the tube's zero-point to the bubble's apex-point, and D the horizontal distance from the bubble's apex-point to the staff. Let $d = .5$ inch, $h = 1$ inch, and $D = 600$ feet; then $R = \frac{d}{h} D = \frac{.5}{1} \times 600 = .5 \times 600 = 300$ feet.

Hence the longer the radius the less will be the curvature of the tube, and the more sensible will be the bubble of any deviation of the tangent to the tube's zero-point from the horizontal; because the bubble must move over a greater length of the tube in proportion to any small elevation of either end. In delicate levels the curvature is very small, and the bubble quivers with the slightest touch or tremor; while in levels made for common use the curvature is more rapid, and the bubble is more readily brought to a stand, and remains steadier.

The volume and length of the bubble are affected by every change of temperature. The glass and the liquid both expand—the glass very slightly, the liquid very considerably. If they expand equally, the capacity of the tube and the volume of the liquid would be enlarged in the same proportion, and the volume and length of the bubble would remain always the same. But, as just observed, the dilitation by heat of the glass is only slight, while that of the liquid is very considerable. Hence the capacity of the tube increases much less than the volume of the liquid; and hence the volume and length of the bubble become smaller as the volume of the liquid becomes larger. This may be verified by heating the tube; when, as the liquid receives heat and expands, the volume and length of the bubble will be seen to decrease; and also by cooling the tube, when, as the liquid parts with heat and contracts, the bubble will be seen to increase in volume and length. Alcohol expands regularly $\frac{1}{1800}$ for every degree of heat that it receives above 32°, and it contracts with the like regularity for every degree of heat it parts with below 32°.

In common levels the tubes are used just as they leave the glass factory. Those having an apparent uniform caliber, perceptible convex curvature lengthways, and smooth interior surface, being selected for the purpose; and after the alcohol or the ether is enclosed in sufficient quantity to form a suitable bubble, the ends are hermetically sealed. Now it is evident that if there be any irregularities in the arc against which the bubble runs, they will be imparted to the bubble—one end of which will be broader or narrower than the other, and shorter or longer from the zero-point; and in proportion to the irregularities will the ends of the bubble be unequally distant from that point, and will the tangent thereto deviate from horizontality.

Should the bore of the tube be uneven or irregular curvatures, or should the parts on each side of the zero-point not be symmetrical, the ends of the bubble, as they augment or diminish in length by changes of temperature, would not rest exactly equidistant from the zero-point, or mark equal divisions on the scales. The tangent, however, to the zero-point would be horizontal, although the bubble would have an apparent inclination; and therefore, to bring the ends of the bubble to coincide with the equi-distant divisions of the scales, would be to give the tangent an inclination, and throw the instrument out of adjustment. This results more or less with all unground or defective tubes, and consequently sections plotted, estimates made of work, and works set out and regulated from levels taken or given by such tubes, must be in error in proportion to their imperfection.

In levels of precision, especially those employed for astronomical and engineering purposes, the interior surfaces are made truly even and cylindrical, and with a sensible curvature upwards exactly to an arc of a circle, by grinding them with emery-powder and oil or water on steel cylinders, and then polishing them. This process is repeated until the bubbles prove, by turning the tubes end for end on a delicately-adjusted support, to be perfectly symmetrical, or until the ends appear at, or mark precisely equal distances from the middle or zero-point, the tangent to which is then horizontal.

Hence, in the preparation of these tubes the chief objects to be attained are, uniformity of bore, perfection of curvature, and smoothness of surface; and it should be observed, in conclusion, that whatever care and finish are bestowed on the exterior mountings of the tube, if the interior of the tube itself be imperfect in the above respects, the tangent given by the bubble will not be horizontal. Tubes have been and can be made to indicate a point half a second of a degree from exact horizontality, or within one-hundredth of a foot of horizontality at the distance of one mile. This slight deviation is due, not to the principle of the instrument, but to mechanical defects, from which no instrument, however delicately made, is absolutely free.

MANUFACTURE OF STEEL.

DISCUSSION BEFORE THE SOCIETY OF CIVIL ENGINEERS OF FRANCE.

Translated from "Le Génie Industriel."

An interesting paper upon this subject was presented by M. Galy Cazalat, of which the following is an abstract. This gentleman stated, that in 1851 he made public a process for making, without cost, gases for lighting and heating by causing a jet of steam to pass through a bath of liquid cast iron. This jet produced simultaneously hydrogen gas and steel, the increased value of the latter compensating the cost of producing the gas. He then demonstrated that a jet of saturated steam, alone, could convert, in three or four hours, not more than 200 kilogrammes of steel, which would be heterogeneous and solid. To obtain steel homogeneous and in a liquid state, he conceived, in 1855, the idea of passing simultaneously several currents of compressed air and of superheated steam through several tons of liquid cast iron, which, in less than 30 minutes, would be converted into liquid steel, ready to be poured into molds. After experimenting four years, and having failed to obtain authority to lay down pipes, he was obliged to forego the collection of hydrogen gas.

In 1856, Mr. Martin, of New Jersey, claimed the discovery of a new method of manufacturing steel. His method consisted in permitting melted iron to fall in a fine shower into a deep vessel, through which air was forced. The air rapidly decarburized the small pellets, or threads of iron, converting them into steel, or more frequently into liquid pure iron. To make steel, Mr. Martin added to this product a certain quantity of specular cast iron, thus restoring the requisite carbon.

In 1856, Bessemer presented a method of making wrought iron and steel by passing air or steam through a bath of not exceeding 200 kilogrammes of cast iron.

M. Galy Cazalat showed that, when a jet of ordinary steam is passed through the bath of iron, it will produce only a mass of heterogeneous steel, and will solidify it. The same result will follow when a jet of air is passed through a single pipe, entering any point of a bath of about 200 kilogrammes of cast iron. Indeed, the column of air passing through the liquid metal can be decomposed only at its circumference: the temperature of the metal is raised only by the .21 of oxygen, furnished by the decomposed air, while it is reduced by .79 of nitrogen, to which should be added the volume of air not decomposed. Furthermore, the air cannot touch the more distant molecules of iron, and hence its oxygen cannot burn the carbon they contain. Thus, when the mass solidifies, it is only a mixture of cast iron and steel.

M. Galy Cazalat remarked that it was not until 1861, that Bessemer succeeded in producing the steel now used in the forges.

Comment was made upon this communication by M. Jordan. He thought it might be divided into two heads: 1st. An examination of the antecedents and similitudes of the processes of Galy Cazalat, Martin and Bessemer. 2d. A description of a process for refining iron by steam.

As to the first head, M. Jordan had not studied the patents of M. Galy Cazalat; but he was familiar with his investigations, and desired to render full justice to the ingenuity and perseverance, of which they gave proof. But he believed that M. Galy Cazalat was not accurately informed as to the antecedents of the Bessemer process, which had no relation whatever to refining by steam. It is true that Mr. Bessemer, in 1855, in the first of his patents on the process which bears his name, declared his invention to consist in the injection of threads of air, or of steam, or of air and steam, into the midst, and among the particles of a mass of liquid, crude cast iron, &c.; but in this same patent he asserts, that the injection of steam, having the difficulty of cooling the bath, can be employed only at the commencement of the process, and that the decarburization must be completed by the use of air. M. Jordan is of the opinion that we should not look merely at the specifications of patents to find the history of the phases of an invention which has reached the practical stage, since inventors, to protect their rights, often introduce into them variations altogether untried. It would be far better to study facts. In the famous memoir, read before the British Association, in 1856, which produced a profound sensation among the English metallurgists, refining by steam was not even discussed. Bessemer was well acquainted with the fruitless experiments of Nasmyth, and that distinguished mechanic, who was present at the session, publicly approved the system of refining by air. Neither in the public experiments at Baxter house, in 1856, nor in those at the shops of the Great Northern Railway, was the question of refining by steam raised at all. In truth, there had been no particular effort made in that direction. The difficulties which caused M. Bessemer's works to be withdrawn for a time from public notice, lay in the selection of suitable irons and refractory materials, and, to a slight extent, in the arrangement of the apparatus. The almost immediate success obtained in Sweden, in 1859, in the establishment of Edsken, encouraged Bessemer to persist in his labors, in spite of the contrary opinions of a great majority of English forge masters. The theory of the process, at that time very obscure, began to engage the attention of various Swedish and German metallurgists, and soon it became known how to select coke irons suitable for it, then to recarburize the metal, and at the same time purify it by the addition of spiegeleisen. Success was achieved at Sheffield and at St. Laurin with gray hematite iron from Cumberland. As soon as success had been met with in Sweden, Mr. Bessemer made a communication to the civil engineers of London, and submitted to them many specimens.

However gratifying it might be to national pride, M. Jordan could not agree with M. Galy Cazalat in the assertion that it was by means of the money advanced by the French government to MM. Jackson & Co., that the Bessemer process had become what it now is. MM. Jackson had surely contributed to the perfection of the process; but it must not be forgotten that Mr. Bessemer and his family had expended a fortune of 400,000 francs, before he had reached success, and that MM. Brown & Co., of Sheffield, were manufacturing, with facility, large masses of Bessemer steel, when the process had scarcely been heard of in France.

M. Jordan also believed that M. Galy Cazalat had not been accurately informed, when he attributed to Martin the idea of using specular iron as a recarburizer. The importance of the functions of the carburet of iron and manganese had been pointed out by Heath, in 1839, and the use of specular iron had been announced by Mushet, in 1856. Martin's patents say nothing about it. The cast irons (necessarily gray irons), required by the Bessemer process must contain (under penalty of certain failure), but a slight proportion of manganese. Indeed, they should never contain more than 1 or 1.5 per cent. They should contain 2 to 2.5 per cent of silicium, which is a powerful conservator of heat. The Bessemer irons, manufactured from Algerian ores, contain but little manganese, and the Motka ores contain only 1 to 1.5 per cent. It is erroneous, therefore, to attribute to this metal the success of the Bessemer process, which is due, rather, to the presence of considerable proportions of silicium and carbon, to the absence of notable quantities of manganese, and the almost total absence of phosphorus.

M. Jordan states, that he has not the honor of Mr. Bessemer's personal acquaintance, and that he makes these statements solely in the interest of historic truth.

As to refining by steam, he states that its invention goes back as far as 1855. M. Guineveau, professor of metallurgy in the School of Mines, spoke, some thirty years ago, of a method of refining by steam. In 1840, Mr. Guest, proprietor of the Dowlais establishment, conceived of the injection of steam into the metal of the finery fire. In 1854, Mr. Nasmyth introduced steam into the bath of metal in the puddling furnace, by means of a recurved, hollow rabble. The steam was intended to stir the metal, and being brought into contact with the hot iron, to decompose, furnishing oxygen: this combining with the carbon, sulphur and other oxidizable elements, would eliminate them, while the hydrogen set at liberty would still further desulphurize the mass. The Nasmyth process has been subjected to prolonged trial, and finally abandoned, because the steam reduced the temperature of the bath. The process of M. Galy Cazalat is substantially the same as those of MM. Guest and Nasmyth. M. Jordan was unable to see how, by the use of steam, it was possible to arrive at the production of cast steel. According to the theory, which, it is true, is not definitely settled, as to what is the true reaction at the enormous temperature of the Bessemer process, the metal cannot be decarburized without the formation of much oxide of iron, and yet maintain the exalted temperature necessary to melt the steel. Water, it is true, contains for equal weights, much more oxygen than air. But its decomposition requires the expenditure of a large quantity of heat, which is not re-supplied; and although it may at first manifest its activity at certain points, if the iron is very siliceous, yet the general temperature of the bath is diminished, and the result is, not cast steel, but a mixture of cast, wrought and steely, iron and oxide. This now is the result of M. Jordan's attempts. The great advantage of air is, that it supplies oxygen, without absorbing heat for decomposition. It is probably better even than pure oxygen, of which the reactions would be too violent.

M. Galy Cazalat replied, that Mr. Nasmyth, the inventor of the steam hammer, was opposed to Bessemer in the Society of Civil Engineers of London.

Some metallurgists have asserted, and rightly, that since the invention of the reverberatory furnace, all puddlers are well aware, that the surface of the metal is decarburized by the oxygen of either air or steam: that the new process for making steel consists in causing the air or steam to pass *through* the metal, and this Nasmyth was the first to do—at least with steam. The partizans of the Bessemer process would assert, that the Nasmyth process was intended merely to render less laborious the mixing of the metal by the puddler, who moves about the hearth of the furnace a hollow rabble, through the end of which the steam issues, while the Bessemer process does away with puddling altogether, substituting for it the action of compressed air or saturated steam. M. Galy Cazalat showed that he first conceived the idea of passing steam through baths of zinc, lead and cast iron, in order to produce *without cost* hydrogen gas, through the increased value of oxide of zinc and lead, and especially of steel. He remarked further that nine kilogrammes of steam, which contain, as is well known, 630 calories per kil. bring into the bath 5670 calories. Consequently, their decomposition should absorb $34400 - 5670 = 28730$ units of heat. On the other hand, calculating the effect produced by the 8 kil. of oxygen resulting from the decomposition, and which should combine with the carbon contained in the iron, it will be seen that a kil. of carbon requires, in order to be burned, 2.5 kil. of oxygen, which disengages, in round numbers, 8000 calories, and 8 kil. of oxygen ought to burn $\frac{8}{2.5} = 3.2$ kil. of carbon, disengaging 25000 calories. It follows then, that for 9 kil. of steam, there would be a reduction in heat of 4730 calories; a result directly contrary to all experience, which shows that during the first ten minutes of its flow, the steam raises the temperature of the bath from a red heat, which is 1000°, to the brilliant white, which is 1500°. This false theory, which seems to be stereotyped in the minds of our most accomplished metallurgists, has occasioned, in the last ten years, a loss of several millions to our principal forge masters. He thinks it is about time to correct it by the true theory, founded upon experience, and upon the following chemical and physical principles :

1st. The surface of the bath of iron is decarburized by the contact of an oxide of iron.

2d. A kil. of oxygen, combining with the iron [Fe O], develops 5000 calories.

3d. Cast irons, for conversion into steel, contain about 5 per cent of combined or alloyed carbon.

When superheated steam passes through a bath of iron, it is decomposed into 8 parts of oxygen and 1 part of hydrogen: each kil. of oxygen uniting with the iron, produces 5000 calories. The 9 kil. of steam, therefore, develop 40000 calories, while its decomposition absorbs only 28730 calories. The increment of heat, therefore, is measured by the difference, 11270 calories, which are capable of raising a kil. of iron $11270 \times 3.6 = 40572°$, or 1000 kil. of iron about 40°. Protoxide of iron, containing 8 kil. of oxygen, when brought into contact with the free carbon of the iron, will burn 3.5 kil. of carbon, producing 28000 calories: bearing in mind that, at the extreme temperatures of the process, the heat tends to separate the oxygen from the iron, it must be admitted that the cooling due to this separation, is much less than the heating, measured by 28000 calories.

M. Brull remarked, that he had followed the first experiments of M. Galy Cazalat, at the Imperial foundry at Ruelle, and had had occasion to make a calculation of the number of calorics removed from the bath of cast iron, by the various decompositions, and developed by the combinations, and the calculation, based upon the analysis of the irons employed, had given generally a gain in heat. Moreover, the experiments, notwithstanding divers defects in the details of the plant, which interfered with the success of the operation, yet enabled him to determine that the bath of metal would not cool, but would remain liquid, after the passage of a current of superheated steam. Later experiments have confirmed this result, but have not yielded a constant quality of steel. M. Brull stated that the order of the various phenomena of decomposition and combination of oxides did not affect the final results. It would be sufficient, in estimating the heat developed, to consider merely the various elements in the iron which are burned, and separate from the metal in the form of silicates, without introducing any hypotheses as to the precise manner in which the definite compounds are formed.

M. Depretz remarked that the 34000 calories, developed by the combination of 8 kil. of oxygen and 1 kil. of hydrogen, involved the assumption that the products of combustion be reduced to the zero of temperature. In the experiments cited by M. Galy Cazalat, the steam to be decomposed was under a pressure of two atmospheres, and at the temperature of 600°; each kil., therefore, contained a quantity of heat, which, according to the empirical formulæ of M. Regnault, would be $606.5 + .305 \times 120 + (600 - 120) \times .48 = 873$ calories. The quantity of heat contained in 9 kil. of steam would then be $873 \times 9 = 7857$ calories. To decompose these 9 kil. of water, would therefore take $34000 - 7857 = 26543$ calories, which require for each kil. of oxygen $26543 \div 8 = 3318$ calories. According to the experiments of M. Depretz, upon the oxidation of iron, each kil. of oxygen develops 5325 calories. There is, then, a clear gain of heat equal to $5325 - 3318 = 2007$ (say 2000) calories for each kil. of oxygen.

M. Lencauchez, commenting upon the ideas of M. Galy Cazalat, thought, contrary to the generally received opinion, that the injection of steam into the bath of iron, at a temperature of 10 to 20° above the vaporizing point corresponding to a given pressure, would not occasion a reduction of temperature, but on the contrary, an increase. The quantity of oxygen furnished to the bath being much greater than in the case of atmospheric air, the refining, or more properly the oxidation, of the metal would proceed with great rapidity. The liberated hydrogen could not, in so short a time, reduce the excess of oxide of iron, since the latter is diffused through a large mass of fused metal, which protects the molecule of oxide from the reducing action of the hydrogen. For a similar reason the hydrogen, which is in the nascent state, will not react upon the metalloids (sulphur, phosphorus, arsenic and silicium), which often do not exceed one per cent of the mass under treatment. If the injection of steam be prolonged, the oxide of iron will attack the lining of the vessel, forming multiple silicates, so that the product is neither iron nor steel.

In the following session of the Society, M. Galy Cazalat further stated, that the production of steel by superheated steam had, for ten years, been opposod by the false application of two principles. When 1 kil. of hydrogen combines with 8 kil. of oxygen, it produces water, with evolution of 34462 calories.

Reciprocally, the decomposition of 9 kil. of water into its elements occasions an absorption of 34462 calories.

The conclusion has been, that the decomposition of steam cools the bath which it traverses. But we must account for the union of oxygen with carbon, which restores 25000 calories—a quantity insufficient, it is said, to make steel. He asserts, however, that experience does not confirm this reasoning, but that if a current of dry steam be passed through cast iron at 1200°, it soon raises it to a dazzling white heat. The true theory he asserts to be as follows: Oxygen has a greater affinity for iron than for carbon. Since crude iron contains sixteen times as much iron as carbon, it is with the iron that the oxygen combines, producing a much greater heat than would be the case with atmospheric air, which contains, for equal weights, only one-fourth as much oxygen as water. M. Galy Cazalat enumerated the patents he had received, from 1855 to 1858, for decarburizing cast iron by currents of superheated steam. To obtain a constant production of steel, the iron is first oxidized, then is partially recarburized by the addition of specular iron in crucibles, placed upon the hearth of a reverberatory furnace. In pouring large masses of steel blow-holes would be developed, which it was necessary to reduce under the hammer. He also indicated a method of compressing cast steel in the mold by closing it with a metallic cap, and exploding powder (without sulphur), which was introduced by means of a tube. Long afterwards, Mr. Whitworth conceived the idea of compressing steel by hydrostatic power; but the cannon so made burst, and exhibited blow-holes in all the surfaces of fracture.

He also gave some details for manufacturing, simultaneously, iron and steel, by means of certain minerals contained in volcanic sand from Reunion, Naples and New Zealand. This is a titaniferous, manganic, sesquioxide of iron, containing 80 per cent of oxide of iron, 10 to 12 per cent of titanic acid, and 6 per cent of silica, alumina and lime, and has long been deemed infusible. 50 kil. of this mineral, placed in a graphite crucible has yielded 27 kil. of steel, of which M. Galy Cazalat presented specimens which had been recognized as superior to steels, costing 1,500 francs per ton. The ore is costly by reason of the difficulty of separation from the sands which contain it in small proportions. The separation is effected by crude washing, which yields a sand containing 20 per cent of ore, after the first washing, and 60 per cent after 5 or 6 washings. It is still further eliminated by magnets, until it reaches 80 per cent. M. Galy Cazalat had succeeded in obtaining this ore quite pure, and purposes treating it in a reverberatory furnace, through the roof of which are ten openings, arranged in two lines. By these openings the charge of pig iron is introduced, and when this is melted, plate iron tubes are let down through the openings into the melted bath. These tubes are closed at the lower ends, and coated with an extremely refractory ganister. They are charged with titaniferous ore, which does not melt at the temperature of the furnace, but if a current of air and dry steam be passed into the melted bath, they will agitate it, and give rise to an intense combustion, resulting in an enormous temperature, which melts the ore in the crucible tubes, converting it into a clear, limpid steel, as free from air holes as Krupp's crucible steel. Thus are produced at once, steel in the crucibles, and wrought iron in the furnace, and the operation may be repeated and continued indefinitely.

M. Lencauchez thought the assertions of M. Galy Cazalat were exaggerated. He doubted the ameliorating influence of titanium, and did not think the specimens remarkable. He did not think the proposed apparatus would withstand a series of operations involving such enormous temperatures as M. Galy Cazalat spoke of.

As to the systematic use of powder for reducing blow-holes, he thought it scarcely practicable, and much inferior to the hydrostatic press working at 600 atmospheres. Porous steels are steels poorly made. By using bases which can absorb the oxide of iron produced in the bath, we may escape the reaction of the latter upon the remaining carbon, and thus, the formation of cavities of carbonic oxide. The use of fluxes seemed to him a simple and certain method of obtaining steel free from air holes.

M. Jordan thought it might be advisable, in following up the discussion, commenced at the previous session, upon the communication of M. Galy Cazalat, to explain thoroughly the theory of heating baths of cast iron by intermolecular combustion, in certain systems of refining, and to correct the erroneous opinions which had been disseminated with reference to refining by steam. He also regarded it as his duty to defend the French forgemasters from the charge of having wasted millions of money by adherence to a false theory. He would not revert to the historical questions raised at the last session, and he had spoken of them only because Mr. Bessemer was not represented, and because he believed himself well acquainted with their history, from having studied them conscientiously and impartially. He then read a note upon refining by air, steam and oxygen, treating of the processes respectively of Bessemer, Galy Cazalat and Heaton.

1. With reference to steam.

Assuming that a bath of 1000 kil. of melted gray iron is at the temperature of 1400°, containing* 1000 $(1200\times .17+46+200\times .21)=293000$ calories: it will require 210 calories to produce a variation in temperature of 1°, and the loss of 42000 calories will reduce the iron to the temperature of fusion.

Let us examine successively the combustion of iron, of the carbon, and of the silicium.

Combustion of the iron.—For each centième (10 kil.) of iron burned, there will be required $\frac{10}{3.5}=2.875$ kil. of oxygen, which will produce 12.857 kil. of oxide of iron, developing, according to Dulong, $2.857\times 4327=12362$ calories. The oxide of iron formed, of which the capacity for heat (.17) is very considerably greater than that of wrought iron (.11) will absorb, in order to take the temperature of the bath, at least $(12.857\times .17-10\times .11)\ 1400=1520$ calories.

There will then remain, of available heat from the combustion of the iron, only 10840 calories.

But, to obtain 2.857 kil. of oxygen, there will be necessary 3.214 kil. of vapor of water, containing .357 kil. of hydrogen. This steam, assumed to be dry at 100°, will absorb, in decomposition, $29512\times .357=10538$ calories, and the hydrogen being eliminated after being heated to 1300°, will carry away $.357\times 3.40\times 1300=1578$ calories, making the total loss 12116 calories. The gain in heat being, as above, 10840 calories, it is clear that the bath will ultimately lose 1276 calories for each centième of iron burned by the steam. This loss cannot be re-supplied by superheating the 3.214 kil. of steam, since it would be necessary (the capacity for heat of the steam being .475) to raise it to about 850°, and M. Jordan does not believe that steam can be practically heated beyond 600°.

The combustion of the manganese gives the same results as that of iron.

Combustion of the carbon.—For each 10 kil. of carbon there would be required 13.333 kil. of oxygen to produce 23.333 kil. of carbonic oxide. The combustion may be direct or indirect, that is, effected by the intervention of oxide of iron; but, as Mr. Brull remarked, the quantity of heat developed will always be that due to the formation of carbonic oxide. The result of this combustion will be $10\times 2473=24730$ calories, and the oxide of carbon resulting from 10 kil. of carbon heated to 1400°, will absorb, in elimination, a quantity of heat equal to $(23.333\times .2479-10\times .241)\ 1400=4718$ calories. The gain of heat to the bath will be only $24730-4718=20012$ calories.

To obtain 13.333 kil. of oxygen, there will be required 15 kil. of steam and 1.667 kil. of hydrogen; the decomposition of the former absorbing $1.667\times 29512=.49187$ cal., and the eliminated hydrogen carrying off $1.667\times 3.40\times 1300=7367$ calories. The total loss, therefore, will be $49187+7367=56554$ calories. Hence, the actual loss to the bath will be $56554-20012=36542$ calories.

Combustion of silicium.—For each 10 kil. of silicium there will be required $10\times\frac{25}{21.5}=11.16$ kil. of oxygen, which will form 21.16 kil. of silicic acid, developing 80000 calories, if we admit that the calorific power of sili-

* The temperatures of fusion of various kinds of cast iron are: white iron 1050° C.; graphitic gray iron 1200° C.; gray manganiferous iron 1250° C. The specific heats (capacity for heat):

Wrought iron between 0 and 100°	.109
" " " 0 and 350°	.125
Cast iron, white, slightly carburized	.127
" " " much "	.129
" " gray, between 0 and 200°	.130
" " " " 0 and 1000°	.170
" " " liquid	.210

The latent heat of fusion of ordinary gray iron is 46 calories.

cium is equal to that of carbon completely burned. Silicia acid, by reason of its capacity for heat differing from that of silicium, will absorb a quantity of heat about necessary to bring the 11.16 kil. of oxygen to the temperature of the bath; that is to say, $11.16 \times .218 \times 1300 = 3160$ calories. The bath will then gain 76840 calories. To obtain 11.16 kil. of oxygen will require 12.555 kil. of steam, setting at liberty 1.395 kil. of hydrogen: the heat absorbed by the decomposition being $1.395 \times 29512 = 41169$ cal, and that carried off by the hydrogen $1.395 \times 3.40 \times 1300 = 6166$ calories, the total loss to the bath will be 47335 calories. The total gain, therefore, is 76840—47335 = 29505 calories.

Refining by steam.—Let us now apply the foregoing data to a bath of 1000 kil. of cast iron, of which we will suppose the composition to be similar to that of one of the good Bessemer irons fabricated at the establishments of Terrenoire St. Louis, Givors, &c.

1000 kil. will contain 42.50 kil. of carbon, 20 kil. of silicium, 937.50 kil. of iron and manganese. Suppose the operation to be the regular practice, viz: completely decarburizing, and partially recarburizing. The loss being 15 per cent, we shall obtain 850 kil. of pure iron by burning 87.50 kil. of iron and manganese. Introducing the steam in minutely divided jets, cut off from all extraneous sources of heat, and thoroughly dry, the gains and losses will be:

	Centièmes.	Gain.	Loss.
Silicium	2	59010	......
Carbon	4.25	.....	155303
Iron	8.75	.....	11165
Totals	....	59010	166468
Net loss			107458

The capacity for heat of cast iron being about .16, it will be seen that the temperature of the bath would be reduced more than 650°, without taking into account the exterior cooling of the vessel. The result would be only a mass of pasty iron commingled with oxide and silicate of iron. It is true, that the figures, 107458 calories, above given, are somewhat exaggerated, because the hydrogen and carbonic oxide issuing from the bath are probably at a lower temperature than 1400°; but it will be seen that, assuming this gas to issue at 500° to 600°, the loss of heat will still be more than 60000 calories, and that without accounting for the exterior cooling of the converter, which exercises an important effect.

When an operation of this kind is observed, there will be noted, at first, an increase of temperature, due to the combustion of the silicium, which takes place first: but the commencement of the decarburization reduces the temperature to such a degree that the molecules of the mass lose much of their mobility, the subsequent reactions work badly, and the refining is not completed in a homogeneous manner throughout the mass. Furthermore, in spite of all precautions, an excess of steam will inevitably be introduced, which adds greatly to the rapidity of the cooling. Refining by steam cannot succeed with Bessemer irons any better than with ordinary steel irons (those containing manganese highly carburized and slightly silicized). To avoid a reduction of the theoretic temperature, always less than the real reduction, there is required a cast iron with little carbon, and much silicium; for example, 4 per cent of the latter, and 2 to 3 per cent of the former. But such irons are very exceptional, resulting from a very dry process, which a furnace cannot maintain with impunity. Moreover, as they can be obtained only from ores relatively poor, such as those of the secondary and tertiary formations, they will always contain more or less phosphorus.

It will now be understood why the great establishment of Dowlais, in Wales, after experimenting several months with steam refining, both in the finery fire and puddling furnace, has given it up, notwithstanding the hopes and anticipations of Mr. Guest. Mr. Truran, the engineer of this establishment, asserts that the injection of steam cools the bath. Mr. Nasmyth, the distinguished mechanic, has arrived at the same conclusion. Mr. Percy, professor of metallurgy in the School of Mines at London, who was acquainted with the experiments at Dowlais, and with those of Nasmyth and Parry, also declares that steam will not raise the temperature of the bath. The fruitless attempts in France during the last twelve years have shown nothing contrary to the results previously obtained in England. It has been hoped that, in steam refining, the hydrogen might be utilized in purifying the metal from sulphur and phosphorus. M. Jordan was unaware of any authentic experiments or analyses serving to show that such was the case. He much doubted the efficiency of hydrogen to remove these elements disseminated in small quantities throughout the entire mass. A current of hydrogen passed through a porcelain tube, over sulphur, at a high temperature, is far from converting it completely into sulphydric acid, and if the latter is passed over red-hot iron it parts with the sulphur, as is well known. The affinity of hydrogen for phosphorus is not great.

M. Jordan concluded his remarks by stating, that refining by steam is much inferior to refining by the pneumatic process for the purpose of making steel. He remarked upon the importance of the function of silicium. This is the all-essential element of combustion. Steel makers classify their irons into "cold" and "hot" irons, according as they contain little or much of it. He presented two specimens of iron to the Society; one a gray Bessemer iron—the "hot" variety, containing 2 to 3 per cent of silicium, recognizable by its gray starry grain, smelted at the St. Louis furnaces near Marseilles, for the Imphy Steel Works; the other a specular variety, or spiegeleisen, containing 8 to 10 per cent of manganese, essentially a "cold" iron, easily recognizable by its large crystalline facets, and made at the same furnaces for the steel works on the Loire.

SURMOUNTING RAILWAY INCLINES.

From the "Building News."

To be obliged to start a heavy train upon a stiff incline, in damp weather, when the rails are slippery, or what is technically known as "greasy," is a task hated of engine drivers. If possible, they invariably back on to the level, so as to get a bit of a run at the gradient. In fact, to employ a homely simile, there is exactly the same difference in the two instances referred to as in a man's taking a "standing" and a "running" jump. If the inclines on railways could be so arranged that every ascending gradient should be preceded by a descending one, in other words that the two should meet at the lower level, the impetus acquired in the descent would materially assist the subsequent ascent. There are undoubtedly some instances where this desirable result obtains, but they are, in all probability, occasioned more by accident or necessity than by design. The steeper the incline the greater must be the adhesion of the wheels on the rails. Hence the innumerable patents and inventions for accomplishing this purpose, which climaxed in the introduction of the middle rail and extra wheels. In one sense weight and adhesion are synonymous terms, but to gain the necessary amount of adhesion by simply increasing the weight, would be to employ a remedy worse than the evil, as the difficulty is to get the weight itself up the hill. The experiments at Mont Cenis have quite thrown into the shade anything that has been done at home in the way of surmounting inclines, although we have in latter days distinguished ourselves in the art of making steep railway gradients to a degree that would have appalled our predecessors in that particular branch of engineering. A trial is to be made on the French side of Mont Cenis of the system of an Italian engineer, M. Agudio, for working sharp inclines on mountain summits. This principle has been employed for some years upon the Turin and Gênes Railway, and the experience gained during its application there has enabled the inventor to remedy the imperfections, correct the errors, and introduce those modifications and improvements which are indispensable to the success of every newly-tried mechanical invention.

Steep gradients are essential to the system of M. Agudio. He reconciles the differences of level by inclines of 1 in 10, and presses into his service the resources that nature has placed at his disposal, instead of employing means wholly artificial for accomplishing his purpose. The natural forces or motive power to be found in mountainous districts is utilized by hydraulic machines placed one at the summit, and the other at the bottom of the incline. From these the power is transmitted by the agency of steel telodynamical cables, working at a high velocity, to a locomotive, or, rather, locomotor, which is placed at the head of the train. As no boiler is required, the weight is very small in comparison with that of an ordinary locomotive, being restricted solely to that necessary to provide for the moving parts. At the same time, a certain amount of adhesion is absolutely indispensable, especially on inclines of the steepness already mentioned. In order to effect this, there is, first of all, the weight of the engine. Secondly, this weight is rendered more serviceable by being carried on eight wheels; and, thirdly, there are six horizontal wheels introduced, which by means of springs are caused to press against a central rail, similarly to the well-known Fell system. Powerful brakes are supplied to guard against contingencies in descending the inclines. A grant has been made by the Imperial Government of nearly £10,000 for carrying out this principle at

Mont Cenis, and a similar subvention of the same amount has been given by the Italian Government. The particular section of the Mont Cenis Railway to which this system is to be applied commences at Lanslebourg, a station on the Fell road, crosses the river Arcq, and ascends the sides of the hill by nearly the same route as that occupied by the lines of telegraph. A succession of sharp curves from 450 ft. to 900 ft. radii, and an equal number of heavy gradients, bring the new section to the summit, where it rejoins the line of Fell. This route has been adopted by M. Agudio in order to demonstrate the great advantage of his system over others in use in similar arduous localities. The total difference of level between the starting point and the summit level is 2,296 ft., and this is accomplished in a distance of 2.2 miles, whereas 7.5 miles is the distance required by Mr. Fell to rise the same height. The length of line, and *cæteris paribus*, the cost is, therefore, in the latter instance, about three and a-half times that in the former. One of Fontaine's turbines constitutes the prime motor. It is fed by the waters of the Arcq, which are collected and stored in a reservoir containing 900,000 gallons of that fluid, the whole of which is capable of being run off and replenished six times a day, thus affording six ascents and six descents in the twenty-four hours. Each ascent will occupy about a quarter of an hour, and will of course be made without any interruption *en route*. The load taken up will in round numbers equal sixty tons. It is stated that the Fell locomotive requires an hour to perform the same journey, that is, so far as the difference of level is concerned, and conveys only one-fourth of the load between the same termini. M. Agudio calculates that the ordinary passenger trains, which will weigh considerably less than sixty tons, will "do" the journey in ten minutes. At the present day, when engineers have exchanged the old principle of adapting the road to the locomotive for the more modern practice of suiting the locomotive to the road, any proposed improvement in that direction is deserving of careful and impartial consideration. We trust, in another article, to record the result, and we hope, the success of the proposed experimental line.

STEEL MANUFACTURE.—The discussion before the French Society of Civil Engineers will be read with interest.

ON THE SELECTION OF BUILDING STONES, AND THE CAUSES OF THEIR DECAY.—In the selection of building stones for the exterior walls of a building, *color*, *texture* and *durability* are the objects of the first importance; and all of these ought to be combined to render the structure perfect. Too little attention has been given to the subject of building stones; and while on the one hand we are largely using a brown stone, which gives a sombre, cheerless aspect to the structure, the opposite extreme has been sought in the white marble, or that which is more nearly white in color. In contrast with these, we have the red, glaring color of brick; and it is only partially that this offensive aspect is palliated by painting of neutral tints. In a few eastern cities and towns we find the light gray granites now used in preference to the brown freestone, the white marble, or the dark granite which have been much in use in past years.

No one can fail to experience the sensation of relief afforded by the structures of light colored granites in the city of Boston, or those of the buff or dove colored limestone in the city of Chicago, or of the light gray freestone of many buildings in Cleveland and other places, and of the buff colored brick of Milwaukee. In these cases we have not the excessive reflection of light, or the glare which comes from white buildings, whether of marble or of painted brick, nor the sombre cheerless expression of the darker stone, caused by its great absorption of light. It is only necessary to consider the effects produced by the structures of these different materials upon one's own sensations, in order to determine what are the most agreeable tints, or those which please the eye and produce a cheerful impression upon the mind.

In the majority of structures the necessities of locality, cheapness, or other causes, compel the erection of structures from materials most accessible; but these considerations are not imperative in the case of an important public building.

In many cases where the rock is homogeneous throughout, and the color uniform and satisfactory, it is only to be inquired whether the coloring material is such as will produce decay or disintegration of the particles. When the general color is produced by the aggregation of different materials of distinct coloration, the character of each one is to be considered, and its effect upon the whole; and it is important to have such material comparatively fine-grained, and the different parts as uniformly mingled together as possible. As a general rule, it is only in the darker stones that the coloring matter has any tendency to disintegrate the mass.

In the selection of building stones, the simple presentation of a sample is not enough. The rock in place should be examined in the outset; for in its natural outcrops it has been exposed to the action of the weather, in all its influences, for many thousands of years. One of the principles taught in elementary geology is that the soft and decomposing rocks appear in low rounded or flattened exposures, or entirely covered by the soil or their own debris, forming no conspicuous feature in the country; while on the contrary the harder rocks stand out in relief, producing marked and distinguishing features in the landscape. It not unfrequently happens that the geologist having familiarized himself with the succession and character of the rocks of a particular locality or neighborhood, by seizing the features and character of the prominent beds, is able to trace them in succession along the escarpment or mountain range as far as the eye can reach, and to approach them from any distant point with assurance that he has not been deceived.

The strata which make these features in the landscape are the ever enduring rocks, which have withstood the action of the atmosphere through a period a thousand times longer than any structure of human origin. One cannot doubt that if properly placed in any artificial structure, they would still withstand the action of the elements. These escarpments, in their natural situation, may be coarse, rough and forbidding, more or less dilapidated or unequally dilapidated from the effects of time; but as they there present themselves, we shall be able to see their future in any structure exposed to the same influences.

It is true, however, that no artificial structure or position will ever subject the stone to the same degree of weathering influence to which it is exposed in its natural position, but the same changes in degree will supervene upon any freshly exposed surfaces. In its natural position the bed has been encased in ice, washed by currents, saturated with rains and melting snows, frozen and thawed, and exposed to the extreme of summer heat without mitigation. The rock which has withstood these influences is quite equal to withstand the exposures of a few centuries in an artificial structure. Yet there are occasionally modifying influences and conditions which have sometimes subdued the permanence of a durable stone, and given preference to others less durable. It therefore becomes necessary to carefully examine all these conditions, and to determine not only from the rock in place, but also from its physical constitution, whether it will meet the requirements of the structures proposed.

It not unfrequently happens, in working a quarry, that layers are reached which have not been exposed to the weather, and it is then necessary to test the strength and power of endurance of the stone. This may be done by repeated exposure to freezing and thawing, by testing the strength or power of resistance to pressure, etc. The exposure to freezing and thawing will not only determine its power of resisting the action of the weather, but will determine also whether such foreign ingredients as iron pyrites may exist in the mass. Chemical analysis may be resorted to, for the purpose of comparison with specimens of known composition and durability; but chemical analysis alone cannot determine, without other testing experiments, the strength or power of endurance of the stone.

In some countries, and in certain localities in our own country, the evidence obtained from ancient structures is available in determining the durability of the stone which has been used. Yet it would seem that this information has been of little avail in many places, where the rebuilding of edifices is repealed every century. Experience, in many cases, does not teach the lesson anticipated; and when a dilapidated structure is pointed out, the argument is made that "these stones were not well selected," or they were obtained "at the first opening of the quarry, and were not as good as now furnished." And again, as already remarked, there are few cases in which parties are permitted to select the material without prejudice, the influence of interest, or the absence of important information. Examples are everywhere before us of the improper selection of materials for buildings, and these examples do not deter from their use in the erection of others. When good material is abundant and accessible, it will be used; in other situations, comparatively few durable structures are likely to be erected.—*From Prof. James Hall's Report to the New York Capitol Commission.*

EXPERIMENTAL RESEARCHES ON THE MECHANICAL PROPERTIES OF STEEL.

A paper read before the British Association at Exeter, by WILLIAM FAIRBAIRN, L.L. D., F. R. S.

In my last report I had the honor of submitting to the Association an experimental inquiry into the mechanical properties of steel obtained from different sources of manufacture in the United Kingdom. On that occasion several important experiments were recorded from specimens obtained from the best makers, and bars were received from others, the experiments on which were incomplete at that time. Since then I have had an opportunity of visiting the important works at Barrow-in-Furness, and from these I have received bars and plates of different qualities for the purpose of experiment, and such as would admit of comparison with those recorded in my last report. I have also received specimens from Mr. Heaton for experiment, illustrations of the new process of conversion from crude pig iron—of different grades—to that of steel, as exhibited in the results contained in this report.

In every experimental research connected with metals it is necessary to ascertain as nearly as possible the properties of the ores, the quality of the material, and the processes by which it is proved. On most occasions this information is difficult to obtain, as in every new process of manufacture there is a natural inclination—where the parties are commercially interested—to keep it as long as possible to themselves, and hence the reluctance to furnish particulars.

Of this, however, I can make no complaint, as Mr. Bessenger, the Barrow Company, and Mr. Heaton have, unreservedly, not only opened their works, but they have furnished every particular required, including chemical analyses relative to the properties of the ores, and the processes by which they are reduced.

From this it will be seen that in some of the experiments, I have had the privilege of recording the chemical as well as the mechanical properties of the specimens, which have been forwarded for the purpose of experiments, and of ascertaining their respective and comparative values.

The proprietors of the Barrow Works have confined themselves to certain descriptions of manufacture on the Bessemer principle, these being chiefly steel plates, rails, tyres, and girders. From the nature of the ore and fuel, the latter of which is chiefly brought by rail from the coal fields of Northumberland and Durham, a description of highly refined homogeneous steel is produced, and as this manufacture is intended for purposes where tenacity and flexibility are required, it would not be just to compare it with other descriptions of manufacture where the object to be attained is hardness; such, for instance, as that employed for carriage springs and tools. The description of iron required for rails, beams, girders, &c., is of a different character; tenacity, combined with flexibility, is what is wanted, to which may be added the power to resist impact.

The same may be said of wheel tyres and other constructions where the strains are severe, and where the material is sufficiently ductile to prevent accidents from vibration, or those shocks and blows to which it may be subjected. Keeping these objects in view, the Barrow Company have, to a great extent, been limited to this description of manufacture; and judging from the ductility of the material as exhibited in the experiments, there is little chance of accidents from brittleness when subjected to severe transverse strains, or to the force of impact.

In calculating the value of the hematite steel we have been guided by the same formulæ as adopted for comparison with similar productions from other works. Very few of them, however, would admit of comparison, as no two of them appear to be alike. The hematite steel is manufactured at the Barrow Works for totally different purposes from those of other makers, and, having the command of a variety of ores for selection, as may be seen from the analysis of the ores, as well as the Tables, the desired quality of the steel can be obtained at pleasure.

We have therefore submitted the different specimens to the same tests as those received from other makers, not only for the purpose of ascertaining wherein their powers of resistance differ, but also wherein consists their superiority, as regards deflection, elongation, and compression, from all of which may be inferred the nature and properties of their different structures, and the uses to which they may be applied.

It is for this purpose we have applied the same formulæ of reduction to each particular experiment, as in the other cases, and the results have been embodied in the summaries.

As the Bessemer principle of manufacturing direct from the ore is calculated to produce great improvements and great changes in the production of refined iron and steel, and as the homogeneous properties of the material thus produced are of the very first importance as regards security, &c., it is essential to construction that we should be familiar with the mechanical properties of the material in every form and condition to which it may be employed.

For this purpose I have given all the various forms of strain, excepting torsion, which is of less moment, as the strains already described involve considerations which apply with some extent to that of torsion, and from which may be inferred the fitness of the material for the construction of shafts and other similar articles to which a twisting strain applies.

The great advantage to be derived from the Barrow manufacture of steel, to which we have referred, is its ductility combined with a tensile breaking strain of from 32 to 40 tons per square inch. With these qualities I am informed that the proprictors are able to meet the requirements of a demand to the extent of 1,000 to 1,200 tons of steel per week, which, added to a weekly produce of 4,500 tons of pig iron, enables us to form some idea of the extent of a manufacture destined in all probability to become one of the most important and one of the largest in Great Britain.

In this extended inquiry I have endeavored to deduce true and accurate results from the specimen with which I have been favored by the Barrow Company. In the same manner I have now to direct attention to the product of an entirely new system of manufacture, introduced by Mr. Heaton, of the Langley Mill, near Nottingham.

The experiments on this peculiar manufacture require a separate introductory notice, as the process of conversion is totally different to that of Bessemer, the puddling furnaces, or that of the old system of charcoal beds.

For the finest description of steel, the old process of conversion is still practiced at Sheffield, a fortnight to three weeks being required for the conversion of wrought iron into steel, and, with the exception of Mr. Siemens' reverberatory gas furnace, there had been no improvements made on it, until Mr. Bessemer first announced his invention, by means of which melted pig iron was at once converted into steel.

By the old process the metal was first deprived of its carbon and reduced to the malleable state, when it was rolled into bars and retained from fourteen to twenty-one days in charcoal beds, until it had absorbed, by cementation, the necessary quantity of carbon.

The new process of Mr. Heaton, unlike that either of Mr. Bessemer or cementation, simply deals with the pig iron, and, according to his own statement, eliminates the superfluous carbon, so that steel is in the first place produced, and thence wrought iron of a still further elimination of the carbon.

This is very different to the puddling or the Bessemer processes, of which the former was tedious and expensive, whilst in the latter the pig iron was rendered malleable without any additional fuel, and ready for the hammer or the rolls in a very short space of time.

In so important a branch of metallurgy it would be remarkable if Mr. Bessemer had hit upon the only feasible means of converting iron into steel. Other minds have been inspired in the same direction by Mr. Bessemer's success, and the admixture of metals to effect a transmutation, has been assumed in many forms and proportions, so as to increase our knowledge and lessen the cost of production.

Amongst these is the new process of Mr. Heaton, the detailed description of which is given in a pamphlet by Dr. Miller, a copy of which is annexed. In addition to Dr. Miller's statement, Mr. Robert Mallet reported on the subject, and expressed himself highly sasisfied with the results, both as regards the chemical and physical properties of the metal, and having been present at the experiments made at Mr. Kirkaldy's testing machine, he states the result as under:

	Rupturing strain in tons per sqr. inch of section.	Extension of rupture per cent. of original length
		per in.
Heaton's steel iron.	22.72	21.65
" cast steel.	41.73	7.20

The results recorded in the above Table for cast steel are somewhat below the results obtained in my own experiments, being in the ratio for breaking strain—44.94 : 41.73, or as 1 to .936 nearly.

The whole of these experiments appear to be correct, and assuming the statement of cost to be equally satisfactory, we arrive at the conclusion that, "taking steel from the furnace in ingots, or made into steel rails or bar iron, or in any other form or ordinary manufacture, the net cost of production, after adding 10 per cent for management, including all cost of labor, fuel, and material, and making all allowances for wear and tear, and the like, is *several pounds sterling per ton* under the present market prices of the several descriptions of the metal." And this will be sure to be a matter of surprise when it is taken into consideration that (to repeat the words of Mr. Mallet) "steel can be produced from coarse low-priced brands of crude pig irons, rich in phosphorus and sulphur; thus wrought iron and cast steel of very high quality have been produced from Cleveland and Northamptonshire pig irons rich in phosphorus and sulphur, and every ironmaster knows that first-class wrought iron has not previously been produced from pig iron from either of these districts, nor marketable steel at all. With these observations, I have now to refer to the drawings of the furnaces and apparatus, which I have attached in illustration as an appendix. In conclusion I may state that, looking at this new process, and its further development as a step in advance of that which has already been done by Bessemer and others, we may reasonably look forward to a new and important epoch in the history of metallurgic sciences.

Before entering upon the experiments, it will be necessary to repeat the formulæ of reduction as given in the previous report of 1867. This appears to be the more requisite, as it may be inconvenient to refer to the Transactions of 1867, where it was originally introduced.

Formulæ of Reduction.

For the Reduction of the Experiments on Transverse Strain.

When a bar is supported at the extremeties, and loaded in the middle.

$$E=\frac{w\,l^3}{4\,\delta\,K\,d^2} \quad . \quad . \quad . \quad . \quad . \quad (1).$$

where l is the distance between the supports, K the area of the section of the bar, d its depth, w the weight laid on, added to five-eights the weight of the bar, δ the corresponding deflection, and E the modulus of elasticity.

When the section of a bar is a square,

$$E=\frac{w\,l^3}{4\,\delta\,d^4} \quad . \quad . \quad . \quad . \quad . \quad (2).$$

These formulæ show that the deflection, taken within the elastic limit, for unity of

The names marked thus * are used for making iron by the Bessemer process.

pressure, is a constant, that is, $\frac{\delta}{w}=D$, a constant.

Let $\frac{\delta_1}{w_1}, \frac{\delta_2}{w_2}, \ldots \frac{\delta_n}{w_n}$ be a series of values of D, determined by experiment in a given bar: then,

$$D=\frac{1}{n}\left(\frac{\delta_1}{w^1}+\frac{\delta_2}{w_2}\ldots+\frac{\delta}{w}\right) \quad . . (3),$$

which gires the main value of this constant for a given bar.

Now, for the same material and length,

$$\frac{\delta}{w}, \text{ or } D\ a, \frac{1}{K d^2} \quad . . . . (4).$$

and when the section of the bar is square,

$$\frac{\delta}{w}, \text{ or } D\ a, \frac{1}{d^4} \quad . . . . (5).$$

If D_1 be put for the value of D, when $d=1$, then,

$$D_1=Dd^4.$$

$$=\frac{1}{n}\left(\frac{\delta_1}{w_1}+\frac{\delta_2}{w_2} \quad . . \quad +\frac{\delta_n}{w_n}\right)d^4 \ . (6),$$

which expresses the mean value of the deflection for unity of pressure and section. This mean value, therefore, may be taken as the *measure of the flexibility* of the bar, or as the *modulus of flexure*, since it measures the amount of deflection produced by a unit of pressure for a unity of section.

Substituting this value in *eq.* (2), we get

$$E=\frac{l^3}{4D_1} \quad . . . . (7),$$

which gives the mean value of the modulus of elasticity where D is determined from *eq.* (6).

The work, U, of deflection is expressed by the formula,

$$U=\tfrac{1}{2}\times w\times\frac{\delta}{12}=\frac{w\delta}{24} \quad . . . (8),$$

where δ is the deflection in in. corresponding to the pressure, w in lbs. If w and δ be taken at or near to the elastic limit, then this formula gives the work, or resistance analogous to impact, which the bar may undergo without suffering any injury in its material. This formula reduced to unity of section becomes

$$U=\frac{w\delta}{24K} \quad . . . . (9).$$

If C be a constant determined by experiment for the weight, W, straining the bar up to the limit of elasticity, so that the bar may be able to sustain the load without injury, then

$$\frac{W\,l}{4}=C\,K d \quad . . . . (10),$$

where $C=\frac{1}{6}S$, or $\frac{1}{6}$ of the corresponding resistance of the material per square inch at the upper and lower edges of the section.

$$*{*}*\ C=\frac{4\,Kd}{W\,l} \quad . . . . (11).$$

When the section of the bar is a square,

$$C=\frac{Wl}{4d^3} \quad . . . . (12),$$

which gives the value of C, *the modulus of*

Tensile Strain, &c.

The work, u, expended in the elongation of a uniform bar, 1 ft. in length, and 1 in. in section, is expressed by

$$U=\frac{1}{2} . K . \frac{L}{l}=\frac{1}{2} P_1 l_1 \quad . \quad . \quad (13),$$

where $P_1=\frac{P}{K}$ = the strain in lbs. reduced to unity of section, and $l_1=\frac{l}{L}$ = the corresponding elongation reduced to unity of length.

This value of u, determined for the different bars subjected to experiment, gives a comparative measure of their powers of resistance to a strain analogous to that of impact.

By taking P_1 to represent the crushing pressure per unity of length, and l_1 the corresponding compression per unity of length, the foregoing formula will express the work expended in crushing the bar.

We now proceed to the experiments tabulated in Table No. II, upon a collection of experimental bars, supplied from the Barrow Hematite Steel Company and Langley Mill, ranging from .995 in. to 1,044 in. square, the bearings being 4 ft. 6 in. apart.

The second series of experiments refer to the tensile strength of the steel from the Barrow Hematite Works and from Langley Mill, the length of the specimen being 8 in. and the diameter practically ¾ of an inch. Table No. III, shows the summarized results.

The third series of experiments referred to in Table No. IV, shows the power of resistances of the two classes of steel to compression. The average height of the specimens before experiments was .970, the diameter .72 in., the area being .4071 square inches.

Abstract of Experiments on Hematite Steel.

The strength of these bars, owing to their flexibility, is inferior to the strength of the other Bessemer steel bars before experimented upon. Taking the average of all these latter bars as the mean value of C, the unit of working strength is 5.8 tons; whereas the constant for the hematite bars is 4.2 tons, showing that the former are about one-third stronger than the latter. With about one-seventh more weight laid on the bars, their power of restitution was measured by about two-thirds of the whole deflection, showing that this load was considerably within that requisite to produce rupture. Owing to the high flexibility of the hematite bars, their modulus of elasticity is low. It may be here worthy of observation that for bars of the same length the modulus of elasticity varies inversely as the co-efficient (D_1) of the deflection for unity of pressure and section—that is $E \propto \frac{1}{D_1}$.

These bars underwent a great elongation by a tensile strain, and a large compression by a compressive strain, the average elongation being per unit of length .0792, and that of compression .419; whereas the three numbers for the other bars before experimented upon, did not on an average exceed .06 and .353 respectively, showing the flexibility and superiority of this steel in its powers to resist impact. The average tensile resistance of the bars is about 35 tons per square inch, whereas the resistance of the other Bessemer bars before experimented upon was about 42 tons, so that the tensile strength of the latter is one-fifth greater than that of the former.

The quality of hardness of steel and wrought iron, may be comparatively measured by the amount of extension under a given tensile strain, and the amount of compression under a given compressive strain.

Applying this test to the results of the experiments on the various steel bars, we find that the hardest steel bars were the strongest, *irrespective of the companies by whom they were manufactured.* We find, for example, that the elongation per unit of length for eight of the best Bessemer bars did not exceed .018, and the compression per unit of length did not exceed .25. These bars had a temper probably exceeding that of spring steel, and less than that for tools. The hematite bars are of a totally different description of steel from that manufactured for springs and tools, and this accounts for their comparatively low power of resistance.

Abstract of the Experiments on the Heaton Steel.

This steel being the product of a totally different process of manufacture from that of all the other steel bars previously experimented upon, it is a matter of great importance to know how it stands in relation to them as regards strength and those other properties which are peculiar to steel.

It is for this object that an abstract, separate from the Barrow steel manufacture, has been drawn up.

These bars, in their resistance to a transverse strain, show a very decided superiority over the steel bars before experimented upon. For instance, the mean value of C, the unit of working strength for these bars, is 7.49 tons; whereas the value of the other bars was only 5.746 tons, showing that these bars are 1.3 times stronger than the former bars. The value of U, or the work of deflection for unity of section for these bars, is 90.970, and for the other steel bars before experimented upon it is only 51.696. This value of U exhibits the power of the several bars to resist a force analogous to that of impact. It is therefore clearly shown that this steel must be peculiarly well adapted to resist a force of impact, considering that it is $1\frac{3}{4}$ times superior in the quality than in that of the previous bars.

The flexibility of the steel is somewhat inferior to that of the former bars, the measure of flexibility, D, being for those bars .001345, and for the other bars .001361. The modulus of elasticity is somewhat low for steel, although at the same time it is very little below that for the general average.

This steel, I consider, is well adapted to withstand a severe transverse strain, for it combines the two essential qualities of great strength and powers in its resistance to the force of impact.

The mean breaking tensile strain per square inch of action of this steel is 45.28 tons, whereas the value for the other steel bars before experimented upon is 41.77 tons. The Heaton steel is therefore 1.08 times stronger than the average result given for all the steel produced by other makers. The result, while placing the Heaton steel in a highly satisfactory position when compared with the mean of the whole steel experimented on, places it at the same time below that produced by some of the individual manufacturers.

The elongation of these bars was considerable, and a good deal above the mean for the other bars, thereby giving it a larger value for the work done in breaking the bars.

These bars show high powers of resistance to a compressive strain, all the specimens having undergone the test of 100 tons on the square inch, without any visible external signs of fracture.

From this abstract, it will be seen that this steel, manufactured by Mr. Heaton, stands in the most favorable light in comparison with steel produced by other manufacturers; and if it is taken into consideration that two-thirds of the iron from which the steel was converted was composed of Northamptonshire pig iron, we may reasonably look forward to this invention creating a considerable improvement in the production and the cost of steel.

After a short review of the comparative power of resistance of steel and iron, and the result of some experiments with a steel girder manufactured by the Barrow Hematite Steel Company, the author adds to his paper a detailed description of the furnace and apparatus for the manufacture of steel by the Heaton process, illustrated by diagrams of the same, and the paper concludes as follows:—"It is given by the patentee—and we have no doubt correctly—that the cost per ton of converting crude pig iron into 'crude steel,' exclusive of the cost of the pig, but allowing for the waste upon it at the ratio of 60 lbs. per ton, is £2 4s. per ton, or £1 15s. in crude steel cakes. The cost of making it into 'steel iron' bars *from the pig iron* is £3 10s. per ton of finished bars, and the cost of making into tilted cast steel bars from pig iron is £12 15s. per ton. We have seen the invoices of cast steel bars of this sort sold from Langley Mill at prices equal to those now current at Sheffield for well reputed cast steel made by cementation."

On Roads and Railways as affected by the Abrading and Transporting Power of Water.—The following abstract of a paper before the British Association, by Mr. Logan, on Indian Railways, is from the "Mechanics' Magazine":

The author commenced by stating general conclusions he had arrived at, to the effect that the abrading and transporting power of water was increased directly as the velocity and inversely as the depth; also, that when flowing water had once got its proper load of solid matter in suspension, all erosive action ceased. In short, that it was like a balance, the load being always equal to the power, which power, somehow or other, increased as the velocity became greater, and decreased as the depth of a stream increased, Nature always adjusting the load to the various circumstances. He then gave a short description of the plains and rivers of Northern India, and, by the aid of diagrams, went on to argue that rivers flowing through alluvial plains were raising rather than lowering their beds, and, though this silting-up process may be very slow, yet it was satisfactory to the engineer to know that the foundations of his bridges would be as safe, if not safer, a hundred years hence, as they are now. In speaking of the changes of the courses of rivers, he said that there was more or less a constant cutting going on on the concave banks of a river, with a silting-up process on the opposite side.

The next subject referred to was the denudation of the high level plains of Northern India, called "Doabs" (two waters), and locally known by the name of "Bhanger" land, in contra-distinction to the term "Khadir," or low valley lands, through which the large rivers, fed by the melting snows, now meander. Mr. Logan said that the higher ridges or "back bones" of these Doabs were not caused by any upheavals, but were formed by the denudation of these high level plains; and, as the rainfall was three or four times as great in the valley of the Ganges as that of the Indus, these back bones in the plains of the Punjab disappeared, as well as all defined drainage lines some fifty miles below the hills, for the simple reason that the water spread over these plains and was absorbed. To this peculiarity in the Punjab, particular attention was drawn; for Mr. Logan argued that, if standing crops and grass could permit without receiving injury the rain which fell higher up to flow through rather than over those standing crops, surely the same water could flow over an iron rail at very slow velocities, seldom, if ever rising to such a height as to interfere with a locomotive passing over the line; however, if it did, the obstruction could only last for not more than one day in a whole year. By acting on this principle, Mr. Logan believed that hundreds of thousands of pounds can be saved in the construction of railways in Upper India, as no embankments or masonry culverts and bridges would be required in crossing such high level plains as the Bechna Doabs, which he had surveyed; while pounding back these flood waters by embankments, and forcing it to find an escape through culverts, was most costly and dangerous, for it increased the abrading and transporting power of the water at the very point where alone it could do injury, namely, where it crossed the rails.

In support of his argument he quoted actual occurrences. He urged that deep foundations for bridges was the proper mode for spanning the large rivers of India, and that only one opening for both the main stream and the inundation water should be provided; while any little water that might be left behind in the swamps or low grounds which is below the level of the main river, should be drained off by spoon-mouthed syphons.—Speaking of the minor torrents, he briefly referred to another description of bridges, resting on inverts, with deep massive curtain walls, which may, with economy, be introduced in some instances; and concluded by stating that if once the abrading and transporting power of water was more fully investigated, the engineer could proceed with all descriptions of works affected by flowing water with greater confidence and economy, instancing harbors on the Madras coast, which province, from being at present a financial loss to the State, would soon become profitable, both to India and England, by increased commerce.

Sea-going Ships.—Mr. Merrifield read, before the British Association, extracts from the report of the committee on the state of knowledge of stability and sea-going qualities of ships. The report treated at considerable length on the rolling of ships in still water, followed by an account of the mechanism of waves, and an abridgement of what is known on the subject of the rolling of ships in wave water. The report itself being, in reality, a very condensed abstract of our existing knowledge, it would be difficult to make a useful selection for reading.—Meanwhile, it may be stated in general terms that the rolling of a ship in still water, and her behavior in a sea-way, although interdependent, involve very divergent conditions. It seems that the chief point to attend to, to secure easy rolling, is that the natural period of the ship's occillation should not coincide, or nearly coincide, with the period of the waves, and there seems reason to suppose that we already know how, in a rough way, to influence the natural periodic time of the ship, so as to be able to predict nearly in what wave she will and in what wave she will not roll through excessive angles and with excessive quickness. But our knowledge is exceedingly crude and deficient in detail, and even our known means of observation of the height and form of waves are very unsatisfactory. He also read several reasons by Mr. Froude for not agreeing with the committe.—*Mechanics' Magazine.*

FIRE-PROOF CONSTRUCTION.

From a paper read before the New York Chapter of the American Institute of Architects, April 5, 1869, by P. B. Wight, F. A. I. A.

A distinguished member of this body not long since remarked that a fire-proof building was easily defined: "It is a building which cannot burn, and which contains nothing that will burn."

It is very seldom that any building is required for such use that only non-combustible material shall be placed in it; but it is still a fact that fire-proof buildings are often called for, and are needed, wherein large amounts of combustible materials are to be placed.* To supply such a demand is one of the most important problems offered to the architect for solution. Of such buildings are storage warehouses, and stores or shops, wholesale and retail, as well as buildings for certain kinds of manufacturing processes, such as sugar houses and carriage or furniture shops.

Having devised a building of non-combustible material throughout, the question which next arises is, how to keep a conflagration in one part from extending to all the contents of the building? It seems to me, that in buildings for such purposes, the idea of making them only partially fire-proof is not to be considered for a moment, unless perhaps the material contained is so highly inflammable that it would destroy the material of the building, even if it is divided into fire-proof compartments, in which case it seems to be folly to go to the expense of fire-proof materials at all. When you know that no part of your building can burn of itself, it is evident that every atom of it will offer some resistance to the enemy confined within. I believe, too, that it is impossible to smother or choke a fire once commenced, by the use of closed compartments. Accident or carelessness may leave some openings which will facilitate a draught in some unforeseen way. And even supposing that you have shut in your fire by some arrangement of closed compartments, can you give your compartments less air than a charcoal pit? Close it as much as you will, your confined goods, if the barriers are not forced by the immense power generated by the heat, will at last be reduced to charcoal; for you cannot open a door or window upon such a smoldering fire, but that it will instantly burst into flames. Ships have been brought into port with smoldering fires under their closed hatches, which have been in existence for weeks at a time, while but few have been eventually saved under such circumstances, except by scuttling. Such conditions do not exist with regard to buildings; in them there is not the risk of human lives, which may be saved on shipboard only by closing down the hatches, and scuttling is obviously out of the question.

Store-houses are the only class of buildings which admit of division into air-tight compartments, and there is a practical objection to them in even buildings of this class; but few kinds of goods can be preserved without good ventilation. It seems, therefore, that the compartments should be open and accessible from without, but carefully divided from each other. If so, they afford good facilities to those employed in extinguishing fires; and I think that in a building thus arranged there would be a more reasonable chance of a portion of its goods being saved.

The division of buildings into horizontal compartments, rather than vertical ones, is so much more desirable, where land is expensive, that inventors have almost exhausted their ingenuity in devising thoroughly fire-proof floors. It is obvious, however, that the division of a building by vertical fire-proof partitions, is a matter so easy of accomplishment, that it is questionable whether the horizontal division, so beset with practical difficulties, so expensive, and withal so much less to be depended upon, even when the best systems of construction are used, is ever economical, even where ground is expensive. I even question whether it is of any use to build iron floors, or floors with iron supports, for buildings to contain goods; brick piers and groined arches are alone reliable. If you divide horizontally, you must have stairways within and windows on the exterior, both of which welcome the ascending flames. You may enclose your staircase in a fire-proof enclosure, and you may put the heaviest iron shutters on your windows, but you must have doors through which to gain access from your stairways, and you must open your shutters when you want light. There is a contingency that those traps may be set when the enemy comes, and then all your expensive floors represent so much wasted capital.

* But, by combustible material, I do not by any means intend what the insurance companies call hazardous, but dry goods, books and similar things, which will burn independently of the building in which they are contained.

As yet, I believe that no buildings in this vicinity, built purely for storage purposes, have been constructed entirely of fire-proof materials, except the St. John's Depot of the Hudson River Railroad Company. I am not aware that any attempt has been made in these buildings to stop a conflagration among the goods on storage, either by horizontal or vertical compartments. The floors, to be sure, are of iron and brick, non-combustible, but with hoistways; and it is not difficult to conjecture, even supposing that all horizontal openings and iron shutters were closed, what would be the result of a fire raging on one of those floors, hundreds of feet in expanse.

Several fires occurring recently in the Brooklyn warehouses, have warned their owners to take extra precautions, even though none of these warehouses are fire-proof, if I am rightly informed. One of the best is known as the Pierrepont Stores, near the Wall street ferry, and the arrangement of them is well worthy of notice. These are about three hundred feet in length, and are divided into six compartments by fire-proof party walls; the width of each compartment is consequently about fifty feet, and the length about two hundred feet. The floors are of wood, and it would have been useless to make them of iron and brick; for the goods taken in them are mainly sugars, and it would be folly to attempt to arrest a fire of such combustible material in its ascending course, by any practicable devise. But what is most interesting in these buildings is, that each is fortified against its neighbor. Recently the party walls were carried up about six feet above the roofs, and were pierced with embrasures, through which firemen can play from the roof of one buiding upon the flames in another, with perfect safety to themselves. Here is an instance wherein capital would have been wasted on the expensive materials required for fire-proof floors.

It is the duty of the architect, as I conceive it, to guide the capitalist in coming to a decision on such points. If he devises economical methods, his commission is lessened, but thereby so much more capital remains unemployed, but ready for investment in other enterprises. It would be foreign to my subject to enlarge upon this point, and show how much more it is to the interest of the architect to study reasonable economy in his work, especially buildings for business purposes; but I will let the suggestion stand for what it is worth. Perhaps a knowledge of the fact that most members of our profession agree with me in this opinion, would go far towards disarming the misgivings of many a client upon the question of commissions.

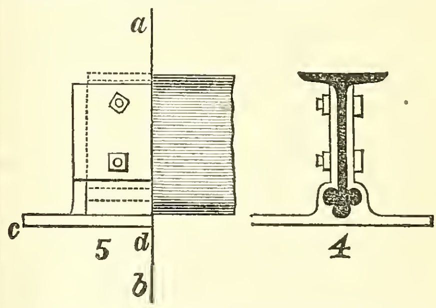
Buildings for manufacturing purposes next demand attention. Some time since a manufacturer and contractor for iron work remarked to me, that if some one would only put up a large fire-proof building, with good steam power, to be rented out for manufacturing purposes, his fortune would easily be made. I have often thought of the suggestion, and wonder why it had not been acted upon. He said that at that time it would be impossible to hire a fire-proof shop or room, with power, in this city. Now, there are many occupations requiring delicate, and not easily replaced machinery, or in which are involved elaborate experiments, running for long periods—the derangement of which could not be recompensed by any amount of insurance—for which a fire-proof building would be almost invaluable. The saving of insurance on such a building and its contents would be greater than the interest on the extra cost of fire-proof floors, and would enable the owner to rent his rooms at a lower rate—in proportion to the equivalent given—than could the owners of buildings with wooden floors. The extra cost of fire-proof construction in a manufacturing building is small when compared with that of a bank or public building. The walls and ceilings require neither lath nor furring, and the floors may be of flags or slate, bedded on the brick arches, or what is better, plates of cast iron bolted to the beams—which will presently be described. All inside finish may be discarded, and iron doors, of No. 16 iron, with light wrought-iron frames, hung to stone templates in the jambs, are the only safe coverings required for the openings.

Such fire-proof buildings, as have been erected for manufacturing purposes, have been specially designed for single occupants. The most perfect and the earliest that I know of, is a building erected on Vestry street, about ten years since, for the Grocers' Sugar Refining Company. This building, as far as its material is concerned, is absolutely fire-proof. It is most remarkable for its floors, which are made of plates of boiler-iron riveted together and secured to the beams in large sheets. This is the most simple system of floor construction I have ever seen, and has many advantages. But I have not seen the building in use, and do not know the floors answer the ends for which they are intended.

Some of the new buildings for the various gas works in this city are fire-proof. The best are those of the Metropolitan Company, at the foot of Forty-second street, North river. But they are, at best, only sheds—brick walls, with iron shutters and roofs. Large, open, and well ventilated, they serve their purposes well; but they can hardly be called architecture.

The most extensive attempt to build a fire-proof building for manufacturing purposes was the enterprise of Harper and Brothers. This was one of the pioneer buildings of the new dispensation. The Harper girder is well known: it is an ornamental cast-iron beam, with a tie rod, and was the father of the truss beam, now so extensively used for supporting the rear walls of stores. It has been succeeded by the built-up beam, now generally used for girders, and the double rolled beam. It was eminently a constructive beam, using iron according to its best properties, cast-iron for compression and wrought-iron for tension. I doubt not that it will some day be again used where girders are required. The built-up beam was invented for the restorers of the "pure" styles, who think that furring strips, laths, plaster, and a modicum of run moldings, not to forget "a neat panel on the soffit," to be a good substitute for the honest lintel of the Greeks, and more artistic than the constructive beam which Mr. Bogardus designed for the Harpers. When men are no longer ashamed to display good iron construction, and bend their artistic conceptions to their constructive skill, we may hope to see something like the Harper beam revived, and decorated in a manner befitting its use.—But I fear that this will be done when a more rational generation than our own holds sway. But to return. In Harpers' building, as in the Cooper building, the deck beam was used for the floors, and brick arches, such as those now in use, were employed. The deck beam has also gone out of use. When first employed, iron beams were not made for houses, but for ships.—The I beam has replaced the deck beam for the former purpose. And in this connection, I would suggest an inquiry into the practicability of using the deck beam inverted.—It has always seemed to me that the broad flange would best sustain compression, and that the roll, having the form of a round bar, would best resist tension. The matter of the bearings is easily remedied by a cast-iron shoe on each end of the beam and bolted to it. This shoe, with a broad foot, would answer the purpose both of template and anchor, and if made to project from the wall and assume an ornamental shape, might become a visible and constructive bracket. The deck beam inverted would evidently present the best appearance from below in cases where the flooring is placed on top of the beams—the various methods of doing which I propose to discuss further on.—Should the deck beam come again into use, it might be made of more ornamental form without detriment to its strength. The bottom roll or flange could be molded in various ways, as is here suggested:

These forms could easily be developed between the rollers. The shoes for the ends of beams might be of this form:*



But, except in so far as the floors are concerned, the Messrs. Harpers' building is far from being fire-proof. There is much woodwork in its inside finish, and the contents being of a highly inflammable nature, I fear that fire would have its own way in that building unless early checked.†

---

* Figs. 4 and 5 represent a section and side elevation of the beam shown in fig. 3 with a cast-iron shoe; *a b* is the face of wall, and *c d* is the bearing of the shoe on the wall.

† An inspection of Harper and Brothers' building, since writing this paper, has convinced me that the principle of division into horizontal compartments has been carried out more thoroughly in it than in any other building of the kind. There are no openings through the floors. It contains neither interior stairs

Of banks and insurance buildings we certainly have a large number which are, to all intents, fire-proof, though but few are thoroughly so. It is generally admitted that such buildings are not in danger from their contents, and to this belief may be ascribed the fact that we already have so many of this class. The Continental Bank, the American Exchange Bank, the Mutual Life Insurance Company's building, the Park Bank and the City Bank building, recently remodelled, are absolutely fire-proof. Nothing less than a bonfire of all the furniture, books and papers that could be collected together in any one room of any of these buildings would endanger its destruction. They are safe from any ordinary casualty. But in all the rest there is enough woodwork to make the word "fire proof," as applied to them, of very doubtful significance. To show what a practical eye the insurance companies have, let me say that in nearly all the so-called fire-proof bank buildings the rates of insurance are as high as in ordinary business buildings. The rates are unusually high in the building which I happen to occupy, on account of a well hole in the center which is trimmed with wood, and would carry a fire through the whole building in an instant. What I might say in relation to buildings of this class will be comprised in some practical suggestions upon fire-proof buildings generally. Let us then look for a few moments into the matter of constructive details.

And, firstly, how shall floors be constructed? Before the "iron period," when our Washington Capitol, our City Hall, our Old Exchange and Custom House were built, the Roman and Mediæval vaults only were used—either of stone or of brick, plastered. When the width of a room was too great for one span, granite columns or brick piers were used, as in our old Exchange, now the Custom House. The floors above the vaults were leveled up and paved with flags or marble tiles. As far as grace, strength, and absolute relief from the dangers of fire were concerned, this was a perfect system. But now space is demanded; there must be no more heavy piers and no great thickness of floors. We are therefore forced to use a material which, though not combustible of itself, will do little work if exposed to great heat; and in this is seen the great difference between our fire-proof buildings of the brick period and those of the iron period, and the inferior fire-proof qualities of the latter. The problem now is to use the minimum of brick and the maximum of iron. I think, therefore, it must be conceded that with the best we can do with this material there is danger; and the problem might be put thus: "Given iron, make as nearly fire-proof buildings as possible out of it." What then has been done with it thus far? For columns, we have used cast tubes of all shapes and sizes, and the wrought iron pillars of the Phœnix Iron Company. For girders, we have used compound beams of cast iron, with wrought ties; built-up beams of various forms of rolled and plate iron, bolted and riveted together; and common rolled beams, used double. For floor beams we first used deck beams for wide spans, and railroad iron for narrow spans; these have now been superseded by the I-beam of various sizes. The rolling mills now have on their circulars I-beams of great dimensions and suitable for girders, but refuse to fill any but large orders; indeed, I believe that only one mill has rollers for beams larger than thirteen inches, while the others will not put up machinery until they get large enough offers. So we are thus far deprived of large smooth beams of one piece for girders of long span—beams which no one would desire to hide from view, but which might honestly tell their use to every beholder. For supports between beams we have had Peter Cooper's terra cotta pots and the four inch brick arches. The former are out of use, and the latter are almost universally employed. Corrugated iron—first used in the Columbian Insurance building by Mr. Diaper—has also gone out of use. The destruction of the Fulton Bank, a so-called fire-proof building, sealed its fate as far as floors are concerned.* We have also had the experiment of stone floors in the American Exchange Bank, by Mr. Eidlitz, and repeated by another architect in the Mutual Benefit Life Insurance Building at Newark, N. J. The stone slabs, brick arches, and the Parisian floors—of plaster or concrete bedded upon bar iron gratings inserted between the beams—are the only practical systems of fire-proof floor construction now in use. The only attempt

nor hoistways; both are on the exterior. The stairs are in an isolated tower approached by bridges, and the hoistway is without enclosure. This arrangement is, however, extremely inconvenient.

* That disaster was owing also to the fact that the beams, other than girders, were made only of No. 12 sheet iron with flanges of two-inch angle iron.

to lay the floor *on* the beams of which I have knowledge is in the sugar house before mentioned. This has suggested to me several methods of laying rigid floors upon beams at considerable spaces (three to five feet) from one another. Preliminary to so doing I have suggested the revival of the deck beam, or the I-beam with a better form for the bottom flange, and the adoption of cast iron shoes for the bearings.

The objections to the brick arches are that their great weight requires heavier beams than would otherwise be used, and that the form of their soffits is not beautiful: for they have the appearance of a long succession of little wagon vaults, requiring a resort to the doubtful expedient of furring the ceiling with iron lath. I think it might be objected to the French system of floors that the expense would be too great, plaster being a dear article with us in comparison with its price in France, while our own cement has not the requisite properties to enable it to be substituted, besides being almost equally costly. The stone slabs of Mr. Eidlitz are the only rigid material thus far used successfully with iron beams, and could be used to better advantage if laid *on* the beams rather than resting upon their lower flanges, as is done in the American Exchange Bank. They are doubtless the handsomest material that can be used for this purpose, but are open to the objection of being heavy and expensive—where expense is a question, and utility only is sought—requiring heavy beams and calling for elaborate cutting on the under side. It will be pertinent to our inquiry, therefore, to ask if there are any other rigid materials adaptable to this purpose, and possessing the desired quality of lightness and cheapness. A former draughtsman of mine, now a member of the Institute, first suggested the use of slabs of slate, about two inches in thickness, for spans of four feet, and thicker or thinner in proportion to the distance of the beams from centers. I give his suggestion for what it is worth. But it led me to believe that we would eventually come to cast iron as the practicable material for this purpose, possessing the requisite qualities of lightness and cheapness, and capable of being bolted to the beams, thus answering all the purposes of flooring and bridging. Cast iron plates may be used for flooring in two ways: first, when deafening and finished floor covering are required; second, when neither is required, as in manufacturing buildings, wherein a reasonably smooth flooring is required, and a few planks, laid where workmen habitually stand, will answer the purpose of non-conducters of heat. Experiment must determine the minimum quantity of iron (in proportion to the strength required) to be used in the floor plates. In obtaining the proper form of strength, and to ensure true castings, the bottoms of the plates will naturally be covered with raised flanges, except at the edges where they bear on the beams. These flanges or beams may assume a decorative form, either a plain diaper or a larger pattern, to form a complete design for the ceiling when many of them are combined. By a judicious arrangement of the flanges the actual thickness of the iron may be reduced to three-eights, or a quarter of an inch. When deafening is required, strengthening flanges may also be cast on top of the plates, and consequently the beams can be placed at wide intervals. The flanges on the top will then serve to keep the concrete used for deafening in its place, and avoid the cracks which might occur in a large surface of cement. The deafening may be of any thickness required, and will serve as a bed for the floor tiles. All that is then required for the underside is judicious decoration of the beams and floor-plates. When deafening is not required, as in manufacturing buildings, the tops should be smooth. It has been objected by a manufacturer, to whom I explained this system of construction, that the floors of iron would be too cold for the feet of workmen. But it would be very easy to put down platforms of wood where the men habitually stand. Besides, when the lower story is heated, the stratum of hot air immediately under the ceiling would naturally keep the floor at a higher temperature than that of the air in the room, and the greater conductibility of the iron would rather tend to warm the feet of those who stand upon it. The plates, in all cases being bolted to the flanges of the beams, would serve as bridging for the floors.

By the above described construction of floors, I would attempt to get rid of the obnoxious and expensive iron lath, so generally used. But it is more difficult to avoid their use on side walls, when the walls are to be plastered—and let me say here that there can be no excuse for plastering the side walls in a fire-proof building, except for economy's sake. The easiest and by all means the cheapest expedient when plastering is required is to build four-inch walls, secured to the main exterior walls by iron straps. These will not conflict with the building laws, provided you build your walls thick enough at the outset. There is, however, no better way in which to finish interior walls than to line them with stone or marble, or both combined. Where decorative effect is desired I would use stone with marble panels. Our native quarries now afford stone light enough in color to set at rest all objections that may be made to its use on the score of light. But if those should hold good the material might be marble paneled with marble, the former white and the latter colored. Obviously, the cheapest material for wall covering in natural materials would be slabs of white marble. Let us, then, make some comparison of figures, and see what can be done with this material. Iron lath, of the form generally used, cost 1.25 dols. per foot. Three-coat plastering costs nine cents per foot. A responsible dealer in marble informs me that he will put up inch slabs of Italian veined or Vermont marble for one dollar and a half per foot. Which, then, would you choose, polished marble at 1.50 dols., or plaster, as good in appearance as that in any tenement house, at 1.34 dols.? This is a fair comparison for exterior walls or ceilings. Italian marble slabs can be procured in any quantity, from eight to nine feet long and three feet wide. In a room fifteen feet high, allowing four feet for wainscot and two feet for cornice, you may line your wall with one length of marble.

What treatment do we now give to doors? We build brick jambs with wooden or iron lintels, as if we would trim the doors with wood. We then put up cast iron jambs, rivet to their edges pilasters or architraves of the same material, and then surmount the whole, perhaps, with a cast iron cornice and pediment. Some have gone so far as to inlay the panels of the iron work with bits of colored marble, thus heightening the effect of the already rough finish of the iron, a roughness which the best foundrymen have been unable to prevent, and which it would cost untold money to reduce down to the smoothness of ordinary work in pine wood. In one of the most pretentious houses on Fifth Avenue they are now putting up jambs, architraves, and cornices made of sawn slabs of marble or marble boards in the same manner in which wood and iron have been used. And what does all this amount to? In the category of shams there is no equal to this monstrous succession. You have imitated a Greek or Roman architrave and cornice by a wooden sham, your wooden sham has been imitated by an iron sham, your iron sham has been imitated by a marble sham; and what is the result? You have kept the form all along; you have come back to the original material by a succession of imitations, and have at last a shell without meat, marble carpentry instead of marble architecture. In all the stages of your attempt to revive the old forms you have sham imitations of shams down to the final achievement of your carpenter in marble. Next must follow, I suppose, the imitation-marble vendor, who will crown the whole fabric of shams and give you something which can as much be called architecture as Mr. Shoddy's painted "red backs" and "blue backs" resemble standard literature. I offer no original suggestion to remedy this condition of affairs. Go back to your old Greek, go back to your old Roman models, if you like them, and, seeing how they are built, go and do likewise; but spare us these sham contrivances. Set up your door posts and plant your lintel upon them, whether for exterior or interior use, and carve them to suit your fancy. They will be at least good so long as they be genuine and strong. Then figure up the cost of this kind of work, and see how much you have saved for your clients.

In conclusion, let me urge you to study diligently the various problems affecting this subject which, in your experience, are continually offered for solution. In so doing, look mainly to a practical solution of the questions which may arise, and free yourselves from all consideration of so-called rules of art, which might control you. The development of architectural design was no less affected by local and circumstantial conditions with the ancients than it is with us; but the conditions at the present time are essentially different from and decidedly more various than those which controlled our ancestors, whether of the classic or mediæval period. Whatever may have been achieved by art in those times was the result of, and co-ordinate with the practical solution of problems then offered.

We have ignored the conditions which especially affect us, and the result is that our architecture, for whatever purpose, is without originality, and wholly irrational.

As long as we allow ourselves to be governed by rules of art founded on the experience of the past, and precedents established by conditions which now do not exist, we need hope neither for good construction nor good art. The attempt to engraft the traditions of the past upon the practical work of this century has resulted in failures involving the waste of hundreds of millions of capital in this country alone; I might name from memory a score of buildings, many of them the most prominent, and all the most costly that have been erected, in proof of this assertion. I would commence with our national Capitol, in whose dome may be seen the most flagrant attempt in all modern times to perpetuate a traditionary style in a material entirely different from that in which the style was developed—so different that the foundations under it could not carry the superstructure if it were erected of the material for which it would appear to have been designed; and for want of foundations of sufficient breadth, even to carry the iron work, it has been necessary to carry the whole exterior iron colonnade upon iron brackets, concealed beneath what appears to be the podium for the whole dome, but which is, in reality, a box of thin plates of cast iron, secured to a light framework built out over the roof of the building.

In erecting modern fire-proof buildings, especially in so far as iron work is concerned, all the conditions imposed upon the architect are different from those which existed in past ages. The same may be said of the use of iron in any building. Subserviency to style, when the material used is not such as was the controlling element of that style, is destructive to all good art; for there can be no truly artistic effect except that which is produced by the best use of material, and its decoration in best accordance with its nature. If the use of iron is ever to lead to the erection of buildings worthy of being called works of art, such a result must be attained only by the recognition of this principle.

The best thinkers have doubted whether there can be any such thing as architecture in iron, assuming, of course, that to be called architecture the material must be constructively used; and there is good reason for these doubts. An iron building does not always require the force of gravity to maintain the cohesion of its parts; it possesses such properties that it may be swung in the air or balanced on a single point, if it is necessary so to do. It is a machine admitting of as little decoration as a steam engine or a printing press. If iron alone were used for buildings, constructive necessity and economy combined might lead us to build houses like steam boilers or water tanks.

What has been done thus far toward the erection of iron buildings on constructive principles? We can only recur to the buildings of the Crystal Palace pattern. We had a beautiful one in New York, admirably constructed, and well designed for its purpose; but even that building was decorated in the Moresque style, perhaps as nearly appropriate to the material employed as any that could have been selected. Here originality in treatment failed just where it was wanted. The same constructive principles were involved in the design of this building which would have been involved in the erection of a fire-proof building. In this respect it was a success.

In the erection of fire-proof buildings, we are forced to do the best we can with iron while using it in the most varied capacities; but when its use can be spared, let me entreat you to rid yourselves of it; where it must be employed, use it rationally and constructively; but better not decorate it at all than imitate styles not in harmony with its constructive properties. As all iron must be painted, I am inclined to believe that the best method of decorating it is in colors; for this treatment the iron must be plain and simple, and the colors may be proportionately brilliant. With regard to other materials, I would suggest nothing more than is said above—in all things build rationally. First, let your work be strong and well balanced—no part too heavy—no part too light. Then decorate it in harmony with its constructive features, never concealing materials except where necessary to protect them, and emphasizing the main lines of the construction by ornamentation. Thus only can the great problem of the day be solved, and the fire-proof architecture of the nineteenth century be made worthy of a rational and progressive age.

Since this paper has been printed I have discovered several unintentional errors of statement, which I am glad to have an opportunity to correct. The Harper's building was not the work of Mr. Bogardus, but was designed and built by James L. Jackson and Brother, of this city. In saying that "but one mill has rollers for beams larger than thirteen inches," I should have added that fifteen-inch rolled beams had been made for some time by the Buffalo Union Iron Works. In giving Mr. Diaper credit for having first introduced fire-proof floors of corrugated iron and cement I did not go back far enough in point of time. The first building in which he used this system of floor construction was the old Bank for Savings, in Chambers street, which was torn down some years since.

I should have mentioned, among fire-proof manufacturing buildings for special purposes, the well built—though far from beautiful—building of the Singer Manufacturing Company, in Mott street. I have recently examined it with much interest. This building has stood one of the most severe tests to which a building can be exposed. About a year ago a fire broke out in the lacquering room, which contained a large amount of combustible materials, but, though the fire raged for several hours, the building was not materially injured. The beams in this building are of wrought and cast iron combined—they are a patented invention of the Architectural Iron Works Company—and of section similar to a letter Y inverted. They are placed three feet from centers, and carry four-inch brick arches. I have not seen these beams used elsewhere. I might also have mentioned among fire-proof warehouses the building of the U. S. Warehousing Co., in South Brooklyn, known among grain merchants as "The Iron Elevator."

STEAM CRANE BOILERS.—The increasing number of boilers used for steam crane and other similar portable purposes renders it important that any dangerous defects to which these boilers are liable should be generally known. The explosion of these boilers has become by no means unfrequent; and, as they are now constantly used in the erection of public buildings, and sometimes in close proximity to crowded thoroughfares, the subject becomes of increasing importance. We therefore take the present opportunity of placing before our readers a few points in connection with this class of boilers which are referred to by Mr. Fletcher in a recent report to the Manchester Steam Users' Association. The boiler to which reference was specially made was of the internally-fired vertical class, cylindrical in the external casing, as well as in the internal firebox, and domed on the top, while the flames from the firebox passed off to the chimney through a single central uptake tube, which formed a most important tie between the crown of the firebox and that of the external casing. Boilers of this type are very simple in construction, and well calculated, when new, to resist a high pressure, so that they are very generally adopted. The dimensions of the one under consideration were—height, 8 ft. 9 in.; diameter, 3 ft. 6 in. in the external shell, and 2 ft. 9 in. in the firebox, while the thickness of the plates was 5-16 in., and the load on the safety valve per square inch, 70 lbs. In this boiler there was found a deep groove or furrow running entirely round the inner casing of the firebox at the bottom of the water space, and eating into the metal to a depth varying from 1-8 in. to 3-16 in., so that more than half the strength of the plate was gone. This is not a peculiar case; others very similar have been met with, and especial danger arises from the fact that these grooves are very difficult to detect. They take place so low in the water space as to be very nearly, if not entirely, concealed by the blocking ring at the bottom, while the only opportunity of examining them is through one or two small sight holes cut through the outer casing.

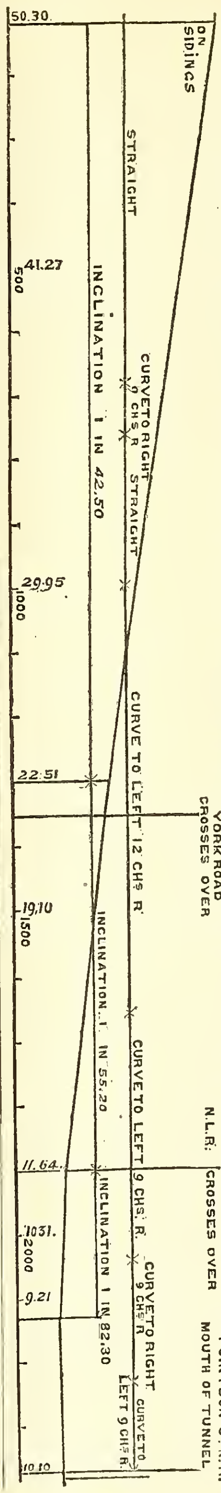
It is frequently supposed that because boilers are small therefore they are safe, whereas the fact of their being small makes them dangerous. Small boilers cannot be inspected as larger ones can, since they do not admit of access for a man, and therefore they are to a greater or less extent apt to be worked on at a risk. The internal examination of portable boilers, so important to their safety, is a question which hitherto has not received that consideration which it deserves, but the subject should no longer be neglected. It is well worthy of the attention of engineers to endeavor to construct such portable boilers as are too small to admit of a man's getting inside so that they may be taken to pieces for examination, and it becomes imperative either that arrangements should be made for doing this, or that these boilers should not be allowed to work on for more than three or five years without being cut open for examination, whatever the inconvenience might be. No doubt if the attention of engineers were directed to this subject, inventive talent would soon construct boilers that could without much difficulty be taken to pieces so as to be examined internally, and thus their safety ensured.—*Mechanics' Magazine.*

WORKING GRADIENTS WITH A RUN.

From "Engineering."

There are few more interesting examples of the utilization of the "work" stored up in a moving mass than that afforded by a railway train mounting by the aid of a "run" an incline up which the attached engine would otherwise be unable to draw it. The spectacle is such a common one to most railway men that probably but few ever devote a second thought to the principle involved in this method of working a gradient, and yet these principles are very simple, and a proper appreciation of them is frequently of considerable use in practice. Under these circumstances we propose devoting a little space to a consideration of this method of working gradients, in the hope that our remarks may be regarded with interest by those who have not hitherto paid the subject the attention it deserves.

A railway train, moving at any given velocity, has stored in it an amount of energy or "work," which, expressed in the ordinary units or foot-pounds, is equal to the weight of the train in pounds multiplied by the height in feet through which a body would have to fall in order to acquire the velocity with which the train is moving. In other words, a train moving at any given speed would, if it were possible to direct its motion directly upwards without checking it, rise into the air to the height from which a body would have to fall to attain the same speed as the train. In practice, it would, of course, be impossible to alter the direction of motion of a train suddenly from a horizontal to a vertical one; but if we suppose, for the present, that the train is exposed to no retardation from friction, the law will equally apply if, instead of the train being made to move directly upwards, it is made to traverse a gradually ascending incline. Let us, for instance, suppose a train to be moving at the rate of 44 ft. per second—a velocity which would be acquired by a body in falling 30.062 ft.,* or say, 30



ft., then that train, if directed on to a rising gradient would, if there were no retardation from friction, ascend that gradient until it reached a point 30 ft. above its original level. If the gradient rose at the rate of 1 in 100, the train would thus mount it for a distance of $30 \times 100 = 3{,}000$ ft., or, if its inclination were 1 in 50, it would traverse it for a distance of $30 \times 50 = 1{,}500$ ft., and so on; the steeper the gradient the less of course being the distance to which the train would have to pass up it to attain the required elevation above the starting point. If the gradient did not rise to the height to which the energy stored in the moving train would be sufficient to carry the latter, then the train on reaching the top of the incline would have a certain residual velocity, this velocity being equal to that which would be acquired by a body in pulling through a space equal to the difference between the rise of the incline and the height to which the train would have mounted. Thus, if we suppose the train moving at a velocity of 44 ft. per second, which we have already taken as an example, to be turned on to an incline rising only 20 ft., it would on reaching the top have a residual velocity equal to that which would be acquired by a body in falling

* The height from which the body must fall *in vacuo*, in order to acquire the given velocity, is, of course, calculated by the ordinary formula, $h = \frac{v^2}{64.4}$; h being the height in feet, and v the velocity in feet per second. For all ordinary practical purposes, the divisor in the above equation may be taken as 64, the formula then being $h = \frac{v^2}{64}$. Similarly, the velocity due to the height fallen is given by the formula $v = 8\sqrt{h}$.

through a space of 30.062—20 = 10.062 ft., or a little over 25 ft. per second.

It follows from what we have already stated that, so long as we suppose the motion of the train to be unretarded by friction, the vertical height to which it will ascend when launched upon a rising gradient at any given speed will be quite independent of the inclination of that gradient. As soon, however, as we take friction into consideration, this law becomes modified, for the flatter the incline the greater will be the distance to which it will have to be traversed by the train in order to attain a certain elevation, and the greater, therefore, will be the space through which the retarding power of friction will be exercised. Arguing upon this fact, it may be considered that, if an incline is to be worked by "taking a run" at it, it will be best to make it as steep as possible, and thus reduce the length necessary for rising a given height; and to a certain extent—but to a certain extent only—this is correct. If a train was allowed to pass suddenly from a level line to a steep gradient, however, a great portion of its energy would be expended in effecting the damage to the rails and rolling stock due to the sudden impact of the wheels with the ascending rails of the gradient, and the more steep that gradient was, the greater the loss due to this cause would be. Even if the very steep incline was united to the level line by a gradient curved in a vertical plane so as gradually to alter the direction of motion of the train, the centrifugal force generated by the passage of the train over this portion of the line at a high speed would materially increase the pressure upon the rails, and thus augment friction. Moreover, it is but seldom that a train is intended to surmount gradients by a "run" alone, it being usually assisted in ascending by the power exerted by an attached engine, and it must be remembered that the shorter the incline the less is the number of revolutions which the wheels of the engine will make in ascending it, and the less, therefore, will be the amount of work which the engine will be capable of developing during the ascent. It will thus be seen that there are, in most cases, practical objections to the employment of inclines much steeper than those in general use.

It may, perhaps, assist in rendering clearer the principles we have been explaining, if we apply them to an actual example; and for this purpose we shall consider the working of the incline connecting the North London and Great Northern lines near King's-cross, the details of which have been kindly furnished to us by Mr. William Adams, of the North London Railway. The incline we have mentioned is altogether 2,016 ft. in length (measured along the gradient), and in this length it rises 41.3 ft., the mean gradient being thus 1 in 48.81. The actual gradient varies, however, as shown in the annexed section, from 1 in 82.3 to 1 in 42.5, and the lower part of the incline is, moreover, curved as marked on the sketch. As far as the question of working the incline with a run is concerned, however, the variation in the rate of inclination is of no consequence, the only matter to be taken into consideration being the length and the total rise. The gradient is worked by engines having 17 in. cylinders, 24 in. stroke, and four coupled wheels 5 ft. 9 in. in diameter, the weight in working order being 42 tons, of which 30 tons rests upon the coupled wheels. These engines take up regularly trains consisting of twenty loaded coal trucks and two brake vans; the trucks weighing 5 tons each and carrying 9 tons of coal, and the brake vans weighing each $8\frac{1}{2}$ tons. The total load, including engine, is thus 339 tons.

In ascending the incline the work to be done consists, first, in actually lifting the 339 tons through a height of 41.3 ft., and, secondly, in overcoming the frictional resistances of the engine and train while traversing the length of the gradient, namely, 2,016 ft. The first mentioned portion of the work, of course, amounts to $339 \times 2240 \times 41.3 = 31,361,568$ foot-pounds, and the second portion may be fairly estimated as follows:

	Lbs.
Frictional resistance of engine at 18 lbs. per ton $= 42 \times 18 =$	756
Frictional resistance of train at 8 lbs. per ton $= 297 \times 8 =$	2,376
Total frictional resistance	3,132

This resistance has to be overcome through a distance of 2,016 ft., corresponding to the exertion of $2,016 \times 3,132 = 6,304,112$ foot-pounds, which, added to the amount due to the actual lifting of the train, makes a total of $31,361,568 + 6,304,112 = 37,665,680$ as the number of foot-pounds of work to be expended in conveying the train up the gradient.

We now come to the question of how this power is to be provided. The engines used exert—as may be calculated by the ordinary rule—a tractive power of 100.5 lbs. for each pound of effective pressure per square inch on the pistons; and as they are worked at a boiler pressure of 160 lbs. per square inch, we may assume that for a short run an effective cylinder pressure of 130 lbs. per square inch could be maintained. Under these circumstances the engine would exert a tractive force of $100.5 \times 130 = 13{,}065$ lbs., and would develop $13{,}065 \times 2{,}016 = 26{,}339{,}040$ foot-pounds of work in ascending the incline. Subtracting this from the total amount of work to be done, as determined above, we get $37{,}665{,}680 - 26{,}339{,}040 = 11{,}326{,}640$ foot-pounds of work as the deficit which is to be made up by the reduction of the speed of the train; and we must now proceed to ascertain from this how great this reduction of speed must be. The total weight of the train is $339 \times 2{,}240 = 759{,}360$ lbs., and dividing 11,326,640 by this number, we find that the deficit to be made up is equal to the lifting of the whole train through a height of $\frac{11{,}326{,}640}{759{,}360} = 14.78$ ft. If, therefore, the train had to merely reach the top of the gradient with no residual velocity, its speed on reaching the foot of the incline would have to be that which would be acquired by a body in falling from a height of 14.78 ft., or a little under 31 ft. per second. In reality, however, the trains have a speed of about 5 miles per hour, or 7.33 ft. per second on reaching the top of the incline; and as this velocity would be acquired by a body in falling through .839 ft., we get $.839 + 14.78 = 15.619$ ft., or, say, 16 ft. as the height corresponding to the velocity which the train should have at the foot of the bank; and the velocity itself would, by the ordinary formula, be 32 ft. per second, or about 21.8 miles per hour.

We have been informed that in practice the speed at which the trains commence ascending the incline is slightly less than we have calculated above, and if this is really the case, the effective pressure on the pistons must be greater than we have assumed, or the friction of the train must be less. A series of indicator diagrams, carefully taken during the ascent of the incline, and accurate observations of the speed of the train on entering and leaving the latter, would give some interesting information which, we think, would be well worth the trouble expended in obtaining it.

The total load of 339 tons, above mentioned, is not the maximum load which the engines have taken up the incline under notice. Mr. Adams informs us that in some instances a load of thirty trucks and two brakes has been taken up, the gross weight of the engine and train in this case being 479 tons. Applying the same mode of calculation to this as to the former example, we get the following results:

	Foot-pounds.
Work to be done in lifting train = $479 \times 2{,}240 \times 41.3 =$	44,318,248
Work to be done in overcoming friction $= 4{,}252 \times 2{,}016 =$	8,572,032
Total	52,885,280
Work done by engine (as before)....	26,339,040
Deficit	26,546,240

This deficit is equal to lifting the whole weight of the train through a space of 24.74 ft., and adding to this .839 ft. as before, we get 25.579 ft. as the height corresponding to the velocity required on entering the bank, and this velocity will thus be, in this case, 40 ft. per second very nearly, or a little over $27\frac{1}{4}$ miles per hour.

VERTICAL WATER TUBE BOILER AND YACHT ENGINE.

From the "Engineer."

We illustrate herewith a very neat boiler and engine for small yachts, patented by Mr. T. Messinger, of Ewell, Kent.

It will be observed that the fire-box is large; it extends to the top of the water tubes, at the same time the bottom ends of these tubes are well down into the flame. The water tubes are placed in a circle round the fire-box, their bottom ends being full open to the side water space, and their top ends full open through the crown of fire-box. A baffle-plate is placed between the tubes, which prevents the flame from at once passing towards the chimney. The flame is thus caused to spread outwards and impinge against the sides of the fire-box, and it envelopes the lower ends of the tubes, striking against them in the best possible manner, viz: at nearly right angles; it is also well split up in passing between the lower ends of the tubes without being extinguished, it then has to pass between the upper parts of the tubes, and before it does so there is ample space between the upper parts of the tubes and the upper parts of the fire-box for the flame to be well expanded, and a second time it strikes the tubes in a good direction, envelopes the upper parts of them in flame, which is well split up a second time in passing between their upper parts. The flame then comes in contact with a coil of copper pipe, through which the feed-water is passing from the pump to the boiler, the water entering cold at the top, in passing down through the coil meets the products of combustion coming upwards; thus the products of combustion, after having twice passed between the water tubes, have to pass from the outside to the inside of this coil and then up through it. The remaining amount of heat is thus well taken up and passed into the boiler in the shape of boiling, or nearly boiling feed-water, and if the boiler and feed-water heater are properly proportioned, the temperature of the products of combustion, before they enter the chimney, will be much reduced; fuel is economized.

It will also be observed that this arrangement of water tubes increases the steaming powers of the fire-box, for supposing these tubes were merely dummies of fire-brick of the same shape, and arranged in the same manner, the heating surface of the fire-box would be greatly improved, as the flame would be more dispersed, and caused to impinge more directly on to the sides instead of merely passing the sides of the fire-box, and going too quickly to the chimney.—Heating surfaces are also more valuable when they are inclined out of the vertical line towards the flame; this is not the case with the fire-box, but it is with the tubes, both at their upper and lower ends. On consideration of the above, it will be seen that all the heating surfaces are exceedingly well disposed to properly receive and transmit the heat to the water, and it was surmised in the design of this boiler that its heating surfaces would be of far more value per square foot than that of other boilers; and the experimental boiler has, we have reason to believe, practically proved this to be correct, for the ratio of fire-grate area to heating surface in this boiler is only as 1 to $20\frac{1}{2}$, whereas in the best locomotive practice it is as 1 to 84. Locomotives having this ratio evaporate from 7 lb. to 8 lb. of water per 1 lb. of fuel, and this boiler, with only one-fourth the ratio of heating surface to fire-grate area, evaporated from 9 lb. to 10 lb. of water per 1 lb. of fuel.

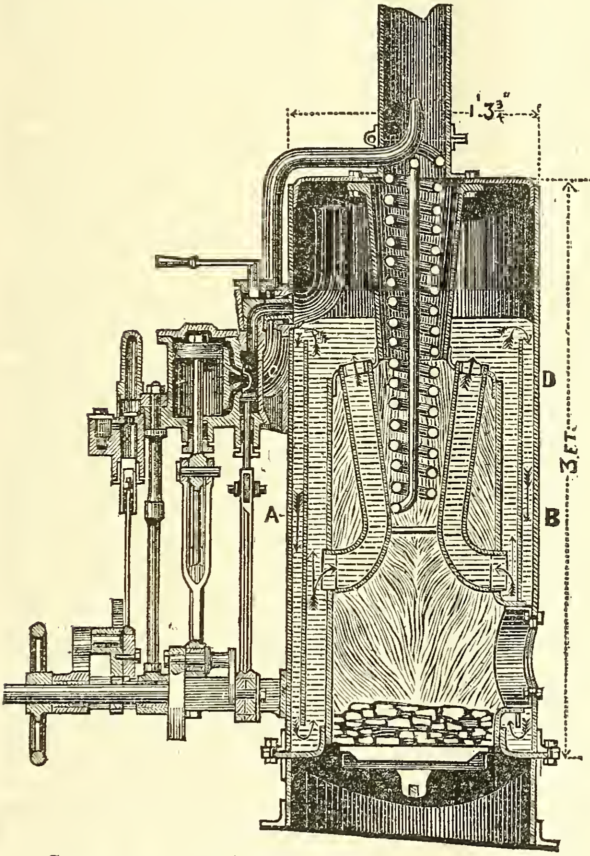
We will now take into consideration the action of the water during the ebullition inside the boiler, and also the generation of steam. It will be seen by the drawing that a cylinder of thin iron is placed in the outer water space, full open at top and bottom; it rests on three legs at the bottom, and is kept in position sideways by a few small distance pieces. This is called the circulating cylinder, because it very greatly assists the natural circulation of water inside the boiler during ebullition. All the water inside this cylinder, both round the fire-box and in the water tubes, being in connection with the heating surfaces, is in a state of violent ebullition. And all the water outside this cylinder, not being in connection with the heating surfaces, is not in a state of ebullition. The water, then, in every part of the boiler inside this cylinder is rapidly carried upwards by the rising bubbles of steam, and, exactly as in a saucepan, tumbles over the edge of the top of this cylinder in a circular waterfall, but it does not, as in the saucepan, tumble over into the fire when it boils over, nor does it commence to prime, but it returns to the bottom of the boiler again down the annular space provided for this purpose contained between the outside of this cylinder and the shell of the boiler, and performs the same circuit over and over again. Therefore there is a rapid upward circulation of water over every part of the heating surfaces, and in the best possible direction, viz: in a line nearly parallel with them, sweeping the clinging bubbles and steam from the plates, and quickly bringing them to the surface, where they readily free themselves from the water into the steam space, and a distinct space is provided outside the circulating cylinder for the return of the water to the bottom of the boiler again.

The arrangement for bolting together is very favorable for cleaning and repairs, especially for small boilers using muddy or salt water. The multitubular boiler generally used for small steam yachts and launches, &c., although generally made to hold a large body of water in proportion to its size, when driven hard is often, in a short time, hopelessly blocked up with scale, and there is no means of getting this out except by the use of strong solutions, which injure the boiler; whereas the boiler illustrated can, in half a day, be taken to pieces, scaled all over by hand, and put together again, and if laid by for the winter, or any other time, may be thoroughly cleaned and tallowed all over inside and out; this will very greatly lengthen its life, for it is often the case that when boilers are laid by for a time they sustain more damage by corrosion than they do when in actual work. The tubes of this boiler having such a rapid circulation of water through them will not give so much trouble by leaking as the fire tubes in the ordinary multitubular boiler do at the fire-box end, and their rapid circulation will, no doubt, greatly reduce the amount of scale deposited on the plates and tubes.

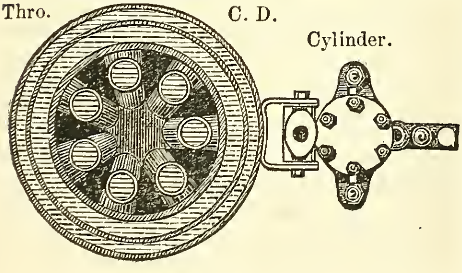
The advantages claimed for this boiler by the inventor are lightness of weight and small dimensions for any given power when compared with any other boiler, simplicity of construction, economy of fuel, small cost of manufacture, and the readiness with which every part can be got at for cleaning or repairs.

The boiler and engine illustrated in the engraving for a steam punt have the following dimensions: Outside diameter of shell, $15\frac{3}{4}$ in.; height of boiler, 3 ft.; fire-grate area, half square foot; heating surface of fire-box, 5 sq. ft; heating surface of tubes, $3\frac{1}{2}$ sq. ft; heating surface of feed-water heater, $1\frac{3}{4}$ sq. ft; diameter of cylinder, 3 in.; stroke, 4 in.; the slide valve, when in full gear, cuts off steam at five-eights of stroke.

Section Elevation of Engine and Boiler.



Sectional plan of Boiler.



During the shop trials, which lasted one month, and were very severe for so small an engine, it was driving a large drilling machine, lathe, shafting, &c., with ease, the engine making 650 revolutions per minute, with a boiler pressure of 50 lbs. Is was impossible to take an indicator diagram on account of the speed, but the dynamometrical power developed in driving a friction brake, was $2\frac{1}{4}$-horse power; and with a consumption of $12\frac{1}{4}$ lbs. of coke per hour, 110 lbs. of water were evaporated per hour, and during the same time with a consumption of 12 lbs. of anthracite coal, 125 lbs. of water were evaporated. This is the average of a number of hours.

The engine, as shown in the drawing, is perfectly self-contained; the cylinder is connected to the framing by an arrangement of three pillars, which take all the working strains of the engine; the brackets by which the engine is attached to the boiler merely have to carry its weight, and the engine can be removed bodily from the boiler and taken all to pieces in a few minutes. As these small engines run at such a high speed, the speed of the pumps is reduced to ensure its regular working by cog wheels, as two and a-half of the engine to one of the pump. In larger engines this gear is not required.

This invention is being introduced by Messrs. Newton, Jenkins & Co., of 4 Westminster-chambers, Victoria street.

THE BIRMINGHAM WIRE GAUGE.

By Latimer Clark.

A paper read before the British Association at Exeter.

In a paper read before the British Association at its meeting in Dundee, 1867, I had the honor of submitting to the members of this section a suggestion to promote the establishment of some universal wire gauge. The gauge which I then ventured specially to recommend, was one approximating very closely to the commonly employed Birmingham wire gauge, and based upon a simple mathematical series, each number representing a weight 25 per cent heavier than the preceding one. Such a scale would, as I then showed, be for a practical purpose sufficiently near to the existing so-called Birmingham wire gauges, as to allow of its being without any inconvenience introduced into trade and manufacture in their stead. At the same time it would always be conveniently reproducible, should ever a reproduction of the normal standard be considered desirable. The history of the present Birmingham wire gauge is as much enveloped in darkness as is the date at which it was introduced, and this is much to be regretted; for had the gauge been determined upon any rational basis, the readiest way would have been to have returned to this basis and reproduced it. In the absence of any definite information, however, to lead us to its origin, it remained only to search in the succession of measures in the gauge itself for internal evidence of the considerations, if any, or at least of the law contemplated or accidental, upon which it was based. In comparing the curve formed by the successive measures of the B. W. G. with that formed by a logarithmic series, it became at once evident, that although very nearly approximate to it, the former measure was not based upon a logarithmic equation, the difference evidently not being one due to difference of constants only. In the logarithmic series, I suggested the relation between the diameters of succeeding makers is throughout as 1 to .8945, whereas in the B. W. G. series, this relation, or if I may be allowed to term it as the factor of reduction, becomes less from .92 in the earlier series, to .82, or thereabout, in the higher ones. At the time from which the B. W. G. probably dates, the manufacturers who then introduced and employed it were not, I think, likely to call in the aid either of mathematical or physical science to supply them with the groundwork of a gauge. Much more probable is it that they took a series of already drawn wires, and constructed their gauge from them.

Before the introduction of steam power, the largest size of iron wire was that now known as No. 1 B. W. G., having a diameter of three-tenths of an inch. From this the next smaller size was drawn at one operation, and from this in turn a still smaller size, until at last the smallest wire had a diameter of a few thousandths of an inch. The most natural way, therefore, by which the wire manufacturers could provide themselves with a gauge would be to call the largest size they could draw No. 1; the next smallest drawn at one operation, No. 2; and so on. In doing so, the relations of the succeeding sizes would be determined between two considerations. On the one hand, the manufacturer would naturally endeavor to draw down at one operation as small as possible, to save labor. On the other, he would be limited in this by the strength of his men, or the machinery in use before the introduction of steam power, and by the cohesive strength of the material itself. Practice would soon show the most profitable mean between these opposing items, and thus the course of manufacture itself would in time supply the workman with a succession of sizes, which he would only need to transfer directly to a measuring plate or calipers, in order to have a gauge adapted to every want of his one individual trade. This I believe to have been the origin of the B. W. G. If this is the case, we should, it is presumable, in investigating the B. W. G. series, find some constant relation between the breaking strength of each wire and the resistance opposed to the draw-plate in drawing it down from its original diameter. Such a relation indeed exists. If we call the diameter of any given number on the gauge D, and the next succeeding one d, the ring section opposed to the draw-plate will be:

$$(D^2-d^2)\frac{\pi}{4}$$

whilst the resistance, R, opposed in drawing by the ring will be:

$$R=r(D^2-d^2)\frac{\pi}{4} \quad . \quad . \quad . \quad . \quad (1)$$

r being the resistance to drawing against each unit of surface. Further, s is the absolute cohesive strength of an unit section of the material. In a hard drawn condition the absolute strength, F, of the wire as it leaves the draw-plate will be:

$$F = s\,d^2\frac{\pi}{4} \quad \ldots\ldots \quad (2)$$

Assuming the relation between the absolute strength of the drawn wire and the resistance of the opposing ring to be a constant one balanced between the item of labor and rapture, say, $\frac{R}{F}=m$; then

$$r\,(D^2 = d^2)\frac{\pi}{4} = m\,s\,d^2\,\frac{\pi}{4}$$

$$d = D\sqrt{\frac{r}{m\,s \times r}}$$

and the factor of reduction, or the relation between the diameter of any wire and that from which it was immediately drawn, would be

$$\frac{d}{D} = \sqrt{\frac{r}{m\,s + r.}} \quad \ldots\ldots \quad (3)$$

The value of s has been exactly determined for almost all substances as their varying qualities and structural irregularites will allow, and is usually expressed as the weight which would rupture a bar 1 in. square. This value is not constant for all sections, being found to increase in some function as the section decreases. Thus a thousand wires, each $\frac{1}{1000}$th of an inch in section, would bear a greater weight than a bar of the metal 1 in. square. The reason of this is, probably, that when drawn out in the form of wire, irregularities of structure which existed in the bar are for the greater part removed, having caused perhaps the rupture of the wires repeatedly in drawing, and the resulting wires having thus been filtered through the draw-plate, are therefore of a superior quality to the bar from which they were drawn. Whatever the cause may be, the fact remains that the co-efficient of cohesive strength of a small wire is greater than that of a large one. Were it not for this we might assume that the value of $\frac{d}{D}$ should be a constant, and the B. W. G. would then be a logarithmic curve. As it is the value of s varying with d, a difference must necessarily be found between the curve representing the B. W. G., and one based upon a logarithmic series. With regard to the value of the natural constant, r, the only determinations, I believe, are those of an Egen, quoted by Mr. H. Thomée in his very valuable paper on gauges read before the Society of German Engineers, in 1866. These determinations are given in the following columns, in which I have converted the resistance from German into English lbs:

						lbs.
1 wire of	248 mils.	drawn down to	220 mils.	required	=	2063
2 "	114	"	101	"	=	400
3 "	101	"	91	"	=	253
4 "	91	"	82	"	=	156
5 "	82	"	72	"	=	164
6 "	72	"	53	"	=	164
7 "	53	"	48	"	=	65

This series of experiments allows us to arrive at an approximate value of the natural constant, r, or the co-efficient of resistance to drawing per square inch of surfaces, as appears in column 6 of the following Table:

No.	D	d	Area of Ring of Resistance.	Force Required	$r=\frac{\text{Force}}{\text{Area.}}$
1	2	3	4	5	6
	mils.	mils.	sq. mils.	lbs.	lb. per sq. in.
1	248	220	×10,290	2063	200,400
2	114	101	× 2,195	400	182,385
3	101	91	1,508	253	167,450
4	91	82	1,198	150	127,162
5	82	72	1,210	164	135,800
6	72	53	954	164	172,125
7	53	38	397	65	138,875
				mean	160,591

Assuming the co-efficient of strength or the cohesion, s, of a bar 1 in. square to be 80,000 lbs. in round numbers, and that this were constant for all sizes of wire, the absolute strength of the foregoing wires would be as follows:

No.	d.	Absolute strength. lbs.
1	220	3041
2	100	641
3	91	520
4	82	422
5	72	326
6	63	249
7	48	145

and the relation of their absolute strengta to their resistances to drawing $\frac{R}{F}$:

1	$\frac{2063}{3041}$	= .678	
2	$\frac{490}{641}$	= .624	
3	$\frac{253}{520}$	= .487	
4	$\frac{156}{422}$	= .370	mean $\frac{R}{F}$=.538
5	$\frac{164}{326}$	= .503	
6	$\frac{164}{249}$	= .659	
7	$\frac{65}{145}$	= .448	

Assuming this mean, .538, to be the probable value of the constant, m, and asserting it in equation, 3, we get the factor of reduction between the two wires.

$$\frac{d}{D}=\sqrt{\frac{1.60591}{9.538\times 80{,}000+160591}}=0.8811.$$

which is about a mean value of the relations throughout the B. W. G. From this agreement it might at first seem obvious that in the above formula if, instead of the mean coefficient of cohesive strength (80,000) we inserted its variable value answering to the various diameters of wires in the gauge, that we should obtain a series of factors of reduction which would give us a perfect reproduction or rectification of the B. W. G. Such would indeed be the case if we could assume any function of variation with any pretense whatever of its being a constant one. It must, however, be recollected that this variation in the apparent cohesive strength is due not to any constant physical property or law of the material experimented on, but solely upon accidental faults in its structure, in fact, upon the badness of its quality, an item which varies in every different sample. The true co-efficient of cohesive strength of any material is, of course, the highest value obtainable for it, being the value nearest to that obtained with a very thin wire. The co-efficient found with larger bars refers not to the material but its faults, and were it not for these faults, wires of all sizes, of the same material, would have the same co-efficient of cohesive strength. The conclusion which we must therefore arrive at is, that the B. W. G. has been formed from a series of sizes of wires drawn from one another, and into which the effects of impurities of metals have entered. Had not this been the case—that is to say, had all the wires from which the B. W. G. series were originally drawn been perfectly pure and homogeneous—there can be no doubt that the succession of numbers would have had a common factor of reduction, and formed, therefore, a logarithmic curve. In reconstructing this gauge, the question forcibly presents itself, are we to allow the effects of accidental impurities in the material to form part of the basis of a widely employed measure; or shall we not rather base it on the assumption of a pure and homogeneous material? An objection might be raised to this, that the origin of the gauge would be limited to the individual properties of a single metal, viz: iron. This is certainly probable, in so far as the origin of the B. W. G. goes; but it would appear that in most metals a constant relation exists between their co-efficients of resistance to drawing out of absolute strength, and this being the case, it becomes probable that had the workers in any other metal determined on a gauge, they would, with the same method, have arrived at the same result.

Karmarsch has given a table of the relative "drawability" of wires of various metals, taking that of hard-drawn steel at 100. Of course this table does not profess to give the exact quantitative values, but it is sufficient to enable us to see that for all the metals contained in it, a constant relation undoubtedly exists between the co-efficients of drawing resistance and absolute strength. I have, therefore, converted Karmarsch's relative values into pounds, by assigning to iron the value usually given it in the tables, and have compared it with the common co-efficient of absolute strength, as follows:

Metal.	Relative "Drawability" given by Karsmarsch.	Calculated Resistance to Drawing, per Square Inch	Absolute Strength.	$\frac{s}{r}$
1	2	3	4	5
Hard-drawn steel...	100	285,000	125,000	.439
" iron...	88	250,000	115,000	.460
" brass..	77	220,000	84,000	.382
Annealed steel......	65	185,000	75,000	.405
Hard drawn copper..	58	165,000	60,000	.363
Annealed brass	46	130,000	57,000	.438
" iron......	42	120,000	56,000	.466
" platinum..	38	108,000	47,000	435
" copper....	38	108,000	49,000	.453
Silver..............	34	97,000	45,000	.464
Gold................	27	77,000	33,000	.428
			Mean...	.430

From values so roughly determined as those given in the second column, the resulting relations found in the fifth column agree sufficiently well to render it a matter of great probability that even a nearer relation exists than that shown here, and therefore that the B. W. G. rectified to a logarithmic series is not confined to the physical properties of iron, but is equally applicable to any of the other metals mentioned.

If the co-efficients of cohesive strength and resistance to drawing were known, and constant magnitudes, nothing would obviously be easier than to construct on the probable basis of the B. W. G. a rational and applicable measure. These co-efficients are, however, so variable with slight differences in the qualities of materials, that the nearest approach we can make to perfection in a scale based upon their relation to each other is by assuming mean values. In the British gauge, which I have had the honor of suggesting, these co-efficients have average values, notwithstanding that I started from a factor of reduction which I assumed only for the reason of its simplicity, as it allows at any part of the scale the weight of the succeeding number to be arrived at by the addition of 25 per cent, and of preceding numbers by the substraction of 25 per cent of the one from which we start. The factor of reduction for diameter being .8945, and the co-efficient of cohesive strength being 80,000,

$$.8945=\sqrt{\frac{r}{.538\times 80,000+r}}$$

whence, $r=172,300$, which is rather higher than the mean value deduced from Egen's experiments. The adoption of some uniform wire gauge has become a pressing necessity of manufacture, and I submit that the B. W. G. re-established on a rational basis, and rectified from the irregularities which have crept into it, partly by want of some recognized standard, and partly by reason of the impurities of the materials from the properties of which it was originally determined, is the best adapted for the wants of the wire gauge. In conclusion, I must call the attention of the British Association to the labor of M. Karmarsch, M. Thomée and M. Peters, towards the establishment of an uniform wire gauge in Germany, whose opinions entirely agree with my own as to the superiority of the English B. W. G. over all the others now in use, and to whose writings I am now indebted for much interesting matter and instructive information on this subject.

THE CLEVELAND ROLLING MILL COMPANY'S STEEL WORKS.—We regret to learn that Mr. John C. Thompson, superintendent of these works, has been compelled, by ill health, to abandon this branch of professional work, at least for the present. He resumes his position in the Croton Aqueduct Department, in New York city. We learn that Mr. Henry S. Nourse, superintendent of the Pennsylvania Steel Works, Harrisburg, is offered and will probably accept the superintendence of the Cleveland Mill.

THE TREATMENT AND UTILIZATION OF SEWAGE.

From the report to the British Association by a commission consisting of the following gentlemen: J. Baily Denton,* Esq., M. Inst., C. E., F. G. S.; Richard B. Grantham,* Esq., M. Inst., C. E., F. G. S., chairman; W. D. Harding, Esq., J. Thornhill Harrison,* Esq., M. Inst., C. E.; J. Benjamin H. Paul,* Ph. D. F. C. S.; Professor Wanklyn, Dr. Gilbert, F. R. S.; Dr. Angus Smith, F. R. S.

Probably one of the most important results of modern scientific inquiry is the general recognition of the fact that attention to the hygienic requirements of towns and populous places has a great influence on the preservation of health and life. Hygienic measures are calculated to prevent disease, and therefore come to be regarded even of more importance than the knowledge gained by two thousand years' experience in the art of medicine. Pure air and water are two of the most essential requirements of all populous places. The removal of water from the surface and from the subsoil by some kind of drainage has been found essential to healthiness of a place; but the thing most of all important in its influence on the sanitary condition of the towns, etc., and as affecting the purity of the air and water, is undoubtedly the mode in which the excretal refuse of their population is dealt with. Even in the most primitive states of society it has always been found necessary to dispose of excreta and other refuse materially from dwellings, in such a manner as to prevent them from becoming a nuisance, and the most simple mode of effecting that object was probably the plan prescribed by Moses to the Jews.

The fact that animal excreta are useful as a manure has also led in many cases to the adoption of some plans of dealing with them for that purpose by which their accumulation in the vicinity of dwellings was prevented to a great extent. In thinly populated places no great difficulty would be experienced in devising simple measures sufficient in that way to meet all requirements, and under such circumstances the mode of effecting the object in view would be a matter to be determined and carried out by the individual residents of a place. But wherever the population became concentrated in villages or towns, difficulties arose as to the disposal of excreta or the immediate removal and use as manure, in consequence of which it became a practice almost universal

* These have only attended the meetings.

to allow them to collect together with other refuse in pits dug in the ground near each house or group of houses, and then at intervals to remove the accumulated contents of these pits for use as manure. As the magnitude of towns increased the difficulty of thus dealing with excretal refuse became greater, and the offensive consequences of its accumulation near dwellings more sensible. Hence the subject became more and more a matter to be dealt with by the local authorities, at first by regulation of the practices adopted by the inhabitants of a place, and eventually as a duty to be provided for and performed by the authorities themselves, in such a manner as to insure the common convenience and well being of the population.

However, the full importance of this subject in other respects was far from being appreciated until within the last thirty or forty years. It is only within this recent period that there has been anything like an adequate recognition of the fact that the sanitary state of dwellings and towns, the health and morality of their population, the condition of rivers, and other matters of importance, are, as a general rule, largely influenced by the practices adopted in regard to excretal refuse. Within that period inquiry and experience have shown that excretal refuse, besides being offensive, and in some cases a great nuisance where accumulated in a state of putrefaction or decay near dwellings, may be, and often is, a source of vast injury to the public health. Opinions may vary as to the precise mode in which that influence is exercised—whether by the evolution of the deleterious gases, by the pollution of water, by the development of those minute organisms which are now very generally considered to be the media of infection, or in all of these ways conjointly; but there is no longer any doubt or difference of opinion as to the general truth that in regard to the mode of dealing with excretal refuse, the sanitary point of view is far more important than any other. If, then, the weightiest question to be solved by a municipal body be—how best to preserve the health and life of the population committed to its charge, it is evident that one of the first duties of such a body is that of providing for the disposal of excretal refuse in a suitable manner. The recognition of this sanitary axiom has been so imperatively enforced during the present century by the frequent prevalence of epidemic diseases, such as cholera and fever, that it may perhaps now be regarded as unquestionable, except where ignorance overcomes intelligence, and where mistaken notions of economy prevail.

Under this aspect the subject has lately attracted very general attention, not only in this country but also in most civilized countries abroad. It will, therefore, be desirable to recite briefly the circumstances under which excretal refuse may become a source of injury to health, and to trace the course events have taken in regard to this subject since public attention was first directed to the sanitary condition of towns, and since measures have been adopted with a view to its amelioration.

Besides the inconvenience and offensive character of the system of collecting excretal refuse in pits or vaults near dwellings, the evils consequent upon that plan arose chiefly from the impregnation of the surrounding soil with decomposing material, and sometimes also from the pollution of water used for domestic purposes. The pit or reservoir was, in some cases, provided with overflow channels or with drains, by which the liquid contents were discharged into a neighboring water-course or into a sewer, but in many cases that was unnecessary, since the soil was of a sufficiently porous nature to admit of the continuous force escape of liquid from the pits. By this natural drainage, according to the nature of the soil, the liquid portion of the excreta would permeate the soil and gain access to the wells, which were, as a very general custom, placed close to the pits where excreta were collected. Moreover, this foul drainage would be augmented, in many cases, by the access of surface water to the pits, especially during wet weather.

These evils were often much aggravated by the absence of any systematic drainage or sewerage of towns sufficient for the removal of subsoil water which became stagnant and putrified beneath the dwellings. Even where underground sewers existed they appeared to have been intended only for the removal of surface water; the connection of house drains with these sewers was prohibited, and it was a penal offense to throw any excretal or other offensive refuse into rivers. At that time the water-closets introduced by Braham, in 1793, were very rarely in use; they had been adopted only in the better class of houses in towns, and then they were used in conjunction with underground vaults for receiving the material discharge from them. Their subsequent more general adoption, and the concurrent acquisition of a better and more copious water supply, were no doubt largely conducive to the health of towns. These changes were attended with a decided aggravation of the evils arising from the use of vaults or pits as receptacles of excreta, for the drainage or overflow from them became continuous on account of the use of water in the closets, and was no longer dependent on the occasional excess of rain. Under these circumstances the pits or vaults became cesspools constantly charged with liquids which in most cases had no outlet into the sewers. Even so late as 1844 the Health of Towns' Commissioners state in their first report that in some of the largest and most crowded towns all entrance into the sewers by house drains or drains from water-closets or cesspools is prohibited "under penalty;" while in other places, including part of the metropolis, the entrance of house drains, was "the concession of a privilege, subjected to regulations and separate proceedings, with attendant expenses," tending to restrict the use of sewers for the purpose of removing excreted refuse or the drainage from pits containing it, or to confine the advantages of this plan to the wealthy.

The removal of the domestic nuisance and inconvenience attending the use of privies and pits for collecting the refuse, by the introduction of water-closets, gave rise in this way to the creation of a town nuisance. The pent-up overflow from cesspools connected with water-closets saturated the subsoil; the town sewers or drains proved inadequate to the duty thrown upon them, for in some instances an improved water supply was taken into a town without any means being provided for taking it out again. The water of wells became permanently polluted; fetid water rose in the cellars of houses, rendering the air impure by its exhalations. Sickness followed, and eventually there arose a louder cry against the cesspool system as an intolerable nuisance, affecting not merely individual houses but the town generally.

The plan proposed as a remedy for this evil was the general introduction of water-closets, combined with a system of thorough town sewerage, the connection of house drains with the sewers being made compulsory on the owners of houses under certain conditions. By these means the necessity for allowing excretal refuse to accumulate at all near dwellings or within towns was to be done away with, and it was to be at once removed from dwellings into the sewers by a copious use of water, and swept rapidly through them out of the town with the waste water from houses and the surface drainage. In this way the water entering a town eventually becomes polluted either by use or by admixture, and thus constitutes what is now commonly termed town sewage, the expeditious removal of which from the vicinity of the town is indispensable for the health of the neighborhood.

This system, known as the water-carriage system, has been largely adopted in this country, and, as a consequence, both the drainage of towns and the removal of the excretal refuse have been in many cases effected by the same means. The utilization of this town sewage as manure by the irrigating of land was contemplated at the outset, but it was not enforced, and it has been carried out only in a few cases, the sewage, as a rule, being discharged from the sewers into any adjoining rivers or into the sea, this being permitted so long as it did not create a nuisance. Individuals or towns injured by the discharge of sewage in this way were left to obtain what redress they could by legal means. The adoption of this system is well known to have given rise to much litigation, and many towns where it has been adopted have been placed in a very difficult position in consequence of injunctions by the Court of Chancery prohibiting the discharge of their sewage. Moreover, the adoption of the water-closet and sewage system of dealing with excretal refuse has been followed by a greatly augmented pollution of rivers, which is now acknowledged to have become an evil of national importance, and is still the subject of an official inquiry. At this point, when the measures adopted for removing successfully the domestic nuisance and the town nuisance arising from the disposal of excretal refuse have given rise to a national nuisance, it has become a very serious matter to determine what is to be done with the sewage of towns. The importance of this question is shown by the fact that besides engaging the attention of the late General Board of Health, besides being frequently discussed in Parliament and by the various local authorities throughout the kingdom, it has, within the last thirteen years, given rise to the appointment of three royal commissions charged with the duties of investigating the subject and of suggesting remedial questions, viz:

(1). The Sewage Commission, dated January 5th, 1857, to inquire into "the best mode of distributing the sewerage of towns and applying it to beneficial and profitable uses," from which three reports have issued, bearing date March, 1858; August, 1861; and March, 1865. The conclusions the commission arrived at were to the effect that the direct application of sewerage to land favorably situated, if judiciously carried out and confined to a suitable area, exclusively grass, is profitable to persons so employing it; that where the conditions are unfavorable, a small payment on the part of the local authorities will restore the balance; that this method of sewage application, conducted with moderate care, is not productive of nuisance or injury to health; that methods of precipitation are satisfactory merely as a means of mitigating a nuisance; that the only radical way of restoring the rivers to their original purity is to prevent the discharge of foul matters into them, and especially the discharge of sewage and other refuse of large towns; that the right way to dispose of towns' sewage is to apply it continuously to land, and that it is only by such application that the pollution of rivers can be avoided; that the magnitude of a town presents no real difficulty to the effectual treatment of a sewage, provided it be considered as a collection of smaller towns.

(2). The Rivers Commission, dated May 13th, 1865, to inquire "how far the present use of rivers for carrying off the sewage" of towns, populous places, &c., can be prevented without "risk to the public health, and how far such sewage, &c., can be utilized," from which three reports have already issued, bearing date March, 1866; May, 1867; and August, 1867; and further reports are expected.

(3). The Royal Sanitary Commission, dated November, 1868, "to inquire into and report on the operation of the sanitary laws for towns, villages and rural districts in Great Britain and Ireland, so far as these laws apply to sewage, drainage, water supply, removal of refuse, prevention of overcrowding, and other conditions conducive to the public health." This latter commission is now engaged in its first proceedings, which are limited to the consolidation and improvement of existing laws, and the establishment of a better recognized central control. It is expected that a preliminary report from this commission will shortly appear.

The object of this committee has been understood by its members as that of supplementing the above mentioned public inquiries with special information as to the local circumstances and practical experience of various towns throughout the kingdom, and with other positive data relating to the subject, such as the Royal Sewage Commission have pointed out as requiring to be ascertained:—"Your committee, on entering on the duties, came to the conclusion that since town sewage, as it is now most commonly known in this country, is a source of nuisance, inconvenience and injury to health, chiefly by reason of its containing the excretal refuse of the population, it was desirable the town sewage should not be restricted to the liquid discharged from sewers in places where there is a thorough system of sewage, combined with water-closets and a copious supply of water, or, in other words, where the water-carriage system of disposing of excretal refuse has been adopted; but that it should for the purposes of the inquiry be understood as comprising excretal refuse in any state." In order to insure an explicit understanding on this point in all correspondence and communications, the following resolution was passed at a meeting of the commission on the 5th of January, 1869, viz:

"That the committee do interpret the word 'sewage' in the instructions of the associations as meaning any refuse from human habitations that may affect the public health—and this interpretation of the term specified in all applications for information. Bearing in mind the circumstances already referred to in the introductory remarks, that formerly towns' sewers were essentially drains, the object of which were simply and exclusively the removal of surface and slop-water by the most direct course to the nearest stream, as well as the fact that such sewers, originally intended only for drainage, have in various ways come to be confounded with and used as sewers for removing excretal refuse, as well as the surface subsoil water, it was for these reasons considered to be especially important to make a marked distinction between drainage and sewerage, and with that object to denote the removal of surface and subsoil water from land by permeable channels, 'as drainage by drains,' and the removal of excretal and other refuse from dwellings, factories, streets, &c., by impervious conduits, or 'sewerage by sewage,' according to the destination, a drain should be understood, or a permeable channel adapted throughout its entire length to remove water from the soil surrounding it; while a sewer should be understood as a channel sufficiently impermeable to be adapted for carrying away refuse without allowing either the refuse to escape through its sides or water to penetrate from without."

One of the first steps taken by the committee was to apply to her Majesty's Secretary of State for the Home Department for his assistance in obtaining information from foreign countries having representatives in England, respecting the practice prevailing abroad for disposing of the refuse of towns, villages, public institutions, factories, dwellings, &c., and having reference to the sanitary condition of the districts in which they are situated, the state of rivers, or the support and increase of the produce of the soil. This application Mr. Secretary Bruce has given effect to by transmitting from time to time very valuable information received from the following countries:—March 15, 1869, from Hamburgh; March 16, from Saxe Coburg Gotha; March 25, from Holland; March 30, from Bavaria; April 14, from Baden; April 26, from Saxony; from Prussia; May 18, from Switzerland; May 20, from Austria and Hungary, from Belgium, from Sweden, from Denmark, from Turkey, from Greece, from Russia, from the United States of America, from Wurtemberg.

It appears from the documents that in most cases, both in town and country places, the use of privies is very general, water-closets being rare even in large towns, and that the usual method of dealing with human excreta is to allow it to collect in pits (*atrills gruben; fossei*), which are sometimes drained, either naturally by the permeable character of the soil, or artificially, so that most or all of the liquid portion of the contents of the pits flows away or infiltrates the surrounding soil. Frequently privies are built over rivers with the object of getting rid of the excreta at once, and at some places methods still more objectionable are adopted, and many houses are without water-closets or privies, and the common custom is to use night-stools, which are emptied into pits near the house. Thus, for instance, in Berlin, with their population under 600,000, there are said to be no less than 50,000 night-stools. Only in some few foreign towns is there any system of sewerage for the removal of excreta by means of water. This is the case with Hamburgh, Paris, Brussels, Hanover, Washington, Philadelphia, San Francisco, and some other American towns to a greater or less extent. In some other towns modified arrangements of the privy and pit system have been to some extent adopted. These consist in substituting for the ordinary pit either a fixed or portable reservoir for receiving the excreta. These reservoirs are sometimes constructed with a drain, by which the overflow of the fluid contents escape, and sometimes they are both water and air-tight, the discharge of the liquid contents into the sewers being prohibited. In some cases such reservoirs are constructed so as to receive only the excreta, and sometimes so as to separate the solid and liquid excreta; but they are also used in combination with water-closets, and sometimes they also receive rain water from the house roofs, &c. The contents of the fixed reservoirs are removed periodically in several different ways, and according to divers local regulations; sometimes their contents are simply dipped out, and sometimes they are removed either by pumping into closed tank-carts, with lift-pumps, or by means of a vacuum previously produced in the tank-cart. In some few cases the time that may elapse between the removal of the contents of these reservoirs is fixed by the local authorities. The portable reservoirs are from time to time removed and replaced with empty reservoirs, then carried outside the town, and their contents used as manure in some way. Both the fixed and portable reservoirs are frequently ventilated by means of shafts rising above the house tops. Fixed reservoirs are used in Carlsruhe, Ostend, Antwerp, Strasbourg, Berlin and Dresden; portable reservoirs are used in Gratz, Dresden, Leipzic, Strasbourg, Berlin and Paris. Generally the contents of pits and of fixed or portable reservoirs are used as manure. In some cases such householders pay for the removal of excretal refuse, in others the contents of pits and reservoirs are sold.

At some places the town authorities pay for the removal of the refuse and street sweepings. Thus in Carlsruhe, a town with about 25,000 inhabitants and 1,400 houses, £500 a year is paid to the contractor for the service, and the contractor sells the manure.

Sometimes a town derives some return from the excretal and other refuse removed and used as manure. In the town of Groningen the yearly profit amounts to about £1,600; in Antwerp it is £2,700; Ostend, £700. In Strasbourg the cost of removal is only just covered by the sale of the manure; the sale of the refuse from the barracks at Carlsruhe, where 2,800 men were quartered, realized a profit of £300 a year, and the attendant expenses amounted to about £40 a year. According to experience in the neighborhood of Berne, Basle, Munich, Zurich, Ghent and other towns where excretal refuse is removed and used as manure, there is always a profit realized after payment of the cost of removal and transport, and it appears to be considered probable that the expenses attending this system would be reduced by the adoption of portable reservoirs. In some other towns the cost of removal and transport exceeds the return; thus in Stockholm, with a population of about 150,000, the expenditure amounts to £35,000 a year, and the income derived from the sale of the refuse as manure £33,000 a year. In Hamburgh there is an extensive system of sewerage, and in a large part of the town the excreta are removed by water-carriage through sewers. In Brussels, Paris, Lausanne and Lugano, the water-carriage system is also more or less in use in some form adapted to local conditions. In the two latter towns water-closets are but rarely used, however, and in Basle, likewise, the privies are situated so as to discharge into the Rhine or into one of its tributaries. In the case of Hamburgh the water of the Elbe is stated to be much polluted by the discharge of sewage, but without any apparent serious influence on health. Statistics furnished by the Secretary to the Hamburgh Board of Health, show, however, that the rate of mortality has kept pace with the increase of population. In 1840, before the construction of the sewerage, the population was 137,000, with a mortality of twenty-eight per thousand. In 1838, the population was 148,000, with a mortality of twenty-two per thousand. In 1859, the population was 174,000, with a mortality of twenty-six per thousand, and in 1866, the population was 195,000, with a mortality of twenty-eight per thousand. The general purport of the communications received from foreign countries is to show that the question as to the means by which excretal refuse may be disposed of and removed from dwellings, villages and towns, so as to prevent nuisance and evil consequences as regards the sanitary condition of the locality, is at least quite as much an open and disputed question as it is in the country. In these documents there is abundant evidence that wherever the subject has been considered there is a strong though vague sense of the injury to health resulting from the accumulation of excretal materials in pits, &c., within populous districts, from the impregnation of the soil, from the pollution of rivers and well water with drainage from such accumulations, and by the discharge of excretal materials into watercourses directly or indirectly; and it appears to be generally admitted that these are serious evils that require to be remedied. Beside these views as to the sanitary aspect of the subject, there is still more decisive evidence of the conviction that a vast quantity of material is now wasted which might be of great service in agriculture for sustaining and augmenting the fertility of cultivated land. There is, however, no instance in which decisive conclusions have been arrived at as to the best mode of dealing with town refuse so as to secure a satisfactory state of public health, and at the same time admit of the agricultural value of that refuse being realized without concurrent disadvantages. It does not appear that any particular improved system of dealing with house refuse has been generally adopted as a substitute for the old practice of collecting such refuse in pits with periodical removal of the contents; neither is there any case where an attempted improvement has been long enough practiced to furnish satisfactory evidence as to the efficacy of the means adopted, and their influence on public health. In both these respects it may be easily said that foreign towns are, as a rule, far behind some towns in this country. The method of removing excretal refuse by pumping it into carts and carrying it out of the towns to the neighboring land, has, in some instances, been continued with satisfaction, while in other instances it has been tried and abandoned. The plan of collecting and removing excretal refuse in portable closed reservoirs has been largely adopted in France, Saxony, Switzerland and other countries, but in no case is any specific information given as to the extent to which the liquid portion escapes spontaneously or by drainage to pollute the adjoining soils and watercourses, or how far the portion of the refuse that remains represents its original value for agriculture. In some towns it is evident that only the solid excreta are used as manure. Thus in Zurich there is a system of sewerage which carries off both the rain-water and liquid drainage from gutters, houses and reservoirs for collecting besides; and probably in most cases where cesspools are fixed and portable reservoirs are in use this greater part of the liquid excreta drains away.

In some towns—as in Berlin for instance—the use of water as a means of transporting the refuse has been proposed, and it is still under consideration. Some of the scientific authorities deputed to inquire into the subject have, however, recommended that any general system of sewerage based on that principle should not be adopted, because of the increased difficulty it gives rise to in the realization of the manure value of the excreta, and because of the anticipated periodical influence on the air of the district where the sewage is applied to land, and upon the water of rivers where the liquid refuse is mixed with them. There does not appear to be in any country general or systematic legislation in reference to sanitary matters; almost everywhere the regulations with that object are in the hands of the police or other local authorities, and though the provisions relating to removals of refuse, cleaning of streets, &c., are often very minute and stringent, they are seldom or ever of such a nature as to deal effectually with those tendencies to unhealthiness which result from the accumulation of excretal and other refuse material, especially in large towns or densely populated districts. As to the precise condition that affects the public health, the connection between the sanitary state of towns and the drainage, water supply, mode of disposing of excretal refuse, &c., there appears to be even more than in this country an absence of definite knowledge or of demonstrative evidence in favor of any particular view; though, at the same time, there is everywhere, in civilized countries, an earnest consideration of these subjects in all their bearings, sanitary, municipal and agricultural.

While this information was being collected from foreign countries, the committee preferred a series of questions with the object of eliciting information as to the several towns, cities and rural districts throughout the United Kingdom, so far as the means at disposal would permit. These questions were sent to 338 local sanitary and sewer authorities, and represent a population of about ten millions. Up to the present time replies have been received from 107 places, having an aggregate population of more than four millions.

Number and population of towns. Town of—	Applied to.	Answered.
Upwards of 100,000	16	8
Between 100,000 and 50,000	23	13
Between 50,000 and 20,000	59	23
Upwards of 10,000	134	33
Rural districts	39	8
Total	338	107

Total area, number of houses, and ratable value of the 107 places from which replies have been received: The total area of seventy-eight of them is stated to be 413,218 acres; the area of the remaining twenty-nine places has not been specified. In ninety-three of these places the total number of houses is stated to be 727,816; and their aggregate ratable value, in fourteen instances no particulars were stated as to this point.

Water supply.—It appears that the sources of water supply in these places are as follows:

	Number of towns.	Aggregate population.
Surface wells	24	354,890
Springs	8	63,680
Gathering grounds	16	1,210,906
Gathering grounds and wells	3	606,552
Gathering grounds and rivers	2	59,000
Rivers and streams	26	843,140
Lakes	1	19,000
Artesian wells	12	263,500
Rivers and surfaee wells	2	446,000
No information given	13	393,740

Of these places, eighty are provided with water-works, twenty-seven without, or give no definite information.

The quantity of water supplied per head of the population is stated to be as under:

	Number of towns.	Aggregate population.
From 50 to 30 gallons	7	596,800
From 30 to 20 gallons	25	1,477,007
From 20 to 15 gallons	13	455,500
From 15 to 10 gallons	15	370,500
Under 10 gallons	3	42,500
Not stated	43	1,444,000

The largest quantity of water supplied is in the case of Lynn, where it is stated to be fifty-six gallons per head daily, and the smallest quantity is said to be supplied in the case of Stroud, where it is only four gallons per head.

Disposal of excretal refuse.—Of the 107 places there are forty-two where the old system of privies with pits for collecting the refuse, is general, and twenty-five where it is partially adhered to. In forty-two places water-closets are general; in twenty-five places they have been adopted partially to a greater or less extent.

Sewage.—Out of the 107 places there are only eleven where no system of sewage exists. In the remainder the sewage of the towns is either general or partial, and in some instances very defective.

	Number of towns.	Houses.	Population.
Completely sewered ..	48	375,002	2,230,578
Partially	48	152,785	1,039,731
Not	11	224,800	145,000
No information	..	....	....
Total	107		

Of the places which are completely sewered there are twenty-nine where water-closets are general, twelve where privies, and seven where both are used. Of the places which are only partially sewered there are twelve where water-closets are general, twenty-two where privies, and fourteen where both are used. Of the places which are not sewered there is one where water-closets are general, six where privies, and three where both are used.

Disposal of liquid sewage and contents of pits, &c.—At seventy-one places out of the 107, the liquid sewage, consisting either of the incharge from water-closets, or the drainage and overflow from pits and cesspools, is discharged into the adjoining stream or river, and in two instances it is discharged into pools of water. At a few of those places the sewage is first submitted to some kind of treatment, chiefly with the object of preventing or mitigating nuisance. At Bury St. Edmunds the liquid sewage is partly got rid of by means of dead wells.

In some places the contents of pits and cesspools are carted away. At fifteen places the liquid sewage is applied to land either wholly or partially, and at two of those places submitted to treatment.

It will be evident that according to local conditions there will be great differences in the nature of the liquid sewage of different places, and that even the contents of pits, cesspools, &c., will vary according as the soil is readily or slightly permeable. The amount of the water supplied, and the admission or exclusion of surface water from the sewer, will also be influenced in this way.

Total quantity and amount of liquid sewage.—Among the ninety-six places where there is a system of sewage, either general or partial, combined with water-closets and a copious supply of water, the minimum daily quantity of liquid sewage discharged varies from 20,000 gallons at Alton, to 17,000,000 at Burmingham, and 130,000,000 at Liverpool.

The storm discharge at places where the surface water is admitted to the sewers, varies from one and a half to twenty times as much as the discharge during dry weather, and in places where the surface water is wholly or partially excluded it varies from one and one-tenth to seven times as much as the dry weather discharge.

The average amount of liquid sewage per head of the population in places where the surface water is admitted to the sewers varies from ten gallons to upwards of 100 gallons, and at places where the surface water is excluded it varies from six gallons to 100 gallons.

Treatment of liquid sewage.—At fifteen of the places which are sewered wholly or partially, the liquid sewage is subjected to treatment either by allowing it to remain for a time in settling tanks from which the deposit is occasionally removed, as at Burton-on-Trent, Birmingham, Epsom, Farnham and Andover, or by filtering, as at Uxbridge and Ealing.

In eight instances deodorizing materials are added, such as lime and carbolic acid, as at Carlisle and Harrow. Lime alone is used at Leicester; lime and chloride of lime at Luton; perchloride of iron at Cheltenham; perchloride of iron and lime at Northhampton; ferruginous clay wetted with sulphuric acid at Stroud; and at Leamington the lime treatment has lately been superseded by the method proposed by Messrs. Sillar and Wigner.

By this treatment the sewage is clarified, and a deposit is separated which is sold as manure.

In regard to the effects thus produced, it is stated that at Leicester the sewage runs off as pure as ordinary rain water; at Ealing it is said to be free from smell, colorless and harmless to vegetable or animal life; at Stroud and Luton the effect is stated to be satisfactory. At Harrow the nuisance is said to be somewhat mitigated, and at Abergavenny the stench is said to be abated by the treatment of this sewage.

At Bury St. Edmunds upward filtration

through charcoal and gypsum has been abandoned in favor of costly irrigation. At Banbury, treatment of the sewage has failed. At Hereford, where it was proposed to be adopted in the parliamentary places, it has not been tried, on the score of expense. At Tunbridge it is about to be tried, and at Hastings and Cambridge experiments are being made.

The cost of treatment amounts, at Leicester, for a population of 7,500, to £300, and the cost of the plant for the purpose was £3,000. At Luton, with a population of 18,000, the annual cost is £500; at Cheltenham, with a population of 36,000, it is £350; at Uxbridge, with 7,000 population, it is £200; and at Alton, with 3,300 population, it is £46.

The solid deposit obtained by treating liquid sewage is sold at prices varying from 6d. to 2s. 6d. per ton. At Leicester as much as 5,000 tons are produced. At Luton the deposit is mixed with night soil, at Banbury with street sweepings, and at Stroud it is made the basis of a manure that is sold at £7 10s. per ton.

After some particulars as to liquid sewage-irrigation, which is carried out in many of the towns of the United Kingdom, the report winds up with the following:

At most places the application of the sewage to land has been found to exercise a most beneficial influence on the condition of the streams and rivers receiving the discharge of the district. At Epsom there was some damage done to the Hogs Mill River, but no complaint is now made. Even where the solid portion of the sewage only is separated by filtration or precipitation, the state of rivers receiving the discharge is improved. At Northampton an application for an injunction has been made by a miller resident on the stream.

Generally speaking, no objection appeared to have been made to the application of sewage for irrigation, and where such objections appeared to have been made on the ground that the application was offensive and injurious, they do not appear to have been supported by medical authorities, and in several instances they have ceased.

As regards the sanitary condition of the district, it appears that in most cases the application of the sewage for irrigation has not been attended with any apparent change, and in several instances there is said to be a marked improvement at Reigate and Brompton. Although the committee feel that the present report deals only partially with the subject of sewage, and is, in fact, only a preliminary step towards the work required to be done, there are two points, viz: the cost of various methods of dealing with excretal refuse, and their influence on the sanitary condition of towns, which it is considered must be referred to, so far as the data obtained will permit.

The removal of the contents of pits and cesspools by cartage appears to be in few instances conducted with some profit; more frequently, however, the cost is at least equal to the return obtained, and very often it is a source of loss. The treatment of liquid sewage does not appear to have advantage in any instance except in lessening the nuisance that would be otherwise caused by the discharge of sewage into rivers, and in most instances it has been a source of loss to the towns where it is practiced. In regard to this point there is a marked difference between the results obtained in this country and those obtained on the Continent, where the removal of the contents of pits is frequently profitable either to individuals or to towns.

The cost of the application of sewage for irrigating land appears to be dependent on a number of local conditions, and, consequently, to vary considerably. It would seem from the data obtained, that in many instances the outlay requisite for this purpose would exceed what a farmer could be expected to incur, and that in such cases at least, it would be proper to regard this outlay as coming under two distinct heads, viz: that which a town may reasonably be expected to bear for the mere object of getting rid of its refuse, and that which a landowner or farmer may be able to incur for the improvement of his land. It is probable that when viewed in this light the application of liquid sewage to land would become a source of revenue to towns only under special favorable circumstances, but that, in opposition to the opinions which have been somewhat hastily formed in certain cases, it will more frequently entail some amount of expenditure on the towns themselves. At the same time the benefit to land and the improvement in the condition of rivers to be realized by the mode of dealing with liquid sewage can scarcely be matter of doubt or uncertainty any longer.

In regard to the sanitary aspect of the subject, it may be regarded as beyond question that the practice of allowing excretal refuse to accumulate and remain for a long time neglected near dwellings in pits, middens, cesspools, or otherwise, is almost invariably accompanied by prejudicial effects on the sanitary condition of the places where it is adopted, either by the impregnation of the soil with decaying material, by the pollution, or by noxious inhalation. But even in places where the water supply has been improved, where a system of sewerage has been adopted, and other measures have been taken with the object of getting rid of the excretal refuse, the fact that the rate of mortality has not been sensibly, if at all, diminished, appears to point to some circumstance as yet insufficiently guarded against, which still exercises a prejudicial influence. The imperfect or defective nature of the sewerage may in some cases be the cause to which this result is referable. But the part of the sewage system which most urgently demands attention at the present time is the ventilation. Gases of a poisonous nature are freely given off from liquid sewage in passages above the sewers from deposits collecting in them and in the house drains. The gases naturally ascend the sewers, and find egress either into the streets of a town or into the dwellings, by means of the house drains and otherwise. The means adopted for getting rid of these gases without injury to the sanitary state of a town, or of the houses in it, are rarely such as to be effective, and the returns already obtained in reference to this matter sufficiently show that attention has not been directed to it in a degree commensurate with its importance. On these grounds the committee consider it would be in the highest degree desirable to institute an inquiry into the nature of the gaseous emanations from sewers in various places.

In reference to the application of liquid sewage to land, they also consider it would be very serviceable to make some inquiry into the nature of the sewage discharged in various places, so as to ascertain the difference that exists in liquid sewage, so far as its value as manure is concerned, and at the same time to endeavor to obtain more definite information as to the cost of removing, and the agricultural value of right as established by practice.

THE FRENCH TRANSATLANTIC COMPANY have contracted to supply their steamers with electric lights. The difficulties of this source of light have been much reduced, and its application looks hopeful.

IRON AND STEEL NOTES.

USE OF STEEL ON THE PENNSYLVANIA RAILWAY.—Steel axles were first introduced, "to secure additional safety," in 1864; and at the end of 1866, 1,907 had been received—600 for passenger and 1,307 for freight cars—the report of their exclusive use under passenger, baggage and express cars, in 1867, being favorable. The number of steel wheels and axles in use during 1868 was 1,042—25 in locomotive trucks, 153 under tenders, and 776 in the passenger and 88 in the freight equipment. Two steel axles out of every hundred are tested under a drop weighing 1,640 lbs., the axle being supported on bearings three feet apart. Passenger axles are required to stand five blows at 30 feet, and freight axles five blows at twenty feet, the axles being turned after each blow.

The use of steel tires was begun in 1861, and in 1866, 62 sets were in use under passenger and freight engines. The first set used ran 103,370 miles (five years' wear) without turning. In 1868, the number used was 327; together with 160 chilled and 15 iron tires, a decrease (217) over 1867, which, the report says, speaks well for the economy of the steel tires. It was early noted that not only are they more durable and safer, but that their adhesive power, even on steel rails, is superior to that of iron tires. On this account they are being tried on the mountain pushers and shifting engines.

The following shows the average mileage per 1-16 inch in thickness wear of tires, on wheels of diameters of 44, 48, 54, 60, and 66 inches:

	44 in. Miles run.	48 in. Miles run.	54 in. Miles run.	60 in. Miles run.	66 in. Miles run.

Chilled Iron	......	6,547	......	......	......

In the twelfth report (1858) the results of experiments with copper fire boxes were given at length, the difference of cost on copper box being $278 less than that of two iron boxes; while its average duration was five years, in comparison with from three to four years for the two iron boxes. Indeed, the first, put on the road in December, 1852, had been in constant use up to Decemeer, 1858; and 22 new ones were introduced during that year. During 1861, 15 were put in, but as the high cost of copper unduly swelled cost of repairs, and as iron boxes would not answer at all, recourse was had that year to a box constructed of homogeneous cast-steel plates. Their use receives favorable mention in the report for 1863; and in 1866, 76 were reported as in service, not one of which had—whether from cracking, leaking of seams or drawing of stay-bolts—failed in any respect, or exhibited perceptible wear. Their success being complete, no others are now built, the number added, in 1868, being 31.—*Chicago Railway Review.*

Aluminium and its Alloys with Iron.—In regard to toughness, the union of 7 per cent of iron with aluminium can scarcely be distinguished from the latter metal when pure. Both metals easily combine with each other. Commercial aluminium mostly, contains iron; it remains ductile with as much as 10 per cent of copper, and when containing only half as much, it may be worked still easier. If alloyed with small quantities of zinc, tin, gold or silver, the metal is rendered hard and more brilliant, but remains ductile. Especially recommended is the alloy, consisting of 97 per cent of aluminium and 3 per cent of zinc. The alloy with 7 per cent of tin can be worked well, but does not take a very fine polish, and cannot be cast, since a more fusible alloy with a large proportion of tin is separated. Aluminium and lead do not unite. The composition, with 3 per cent of silver and 97 of aluminium, possesses a beautiful color, and in equal parts they yield an alloy of the hardness of bronze. The union of 99 per cent of aluminium and one of gold is, though hard, still ductile; its color is that of green gold. With ten per cent of gold the composition is rendered crystalline.

The Ferryhill Furnaces.—Among the most remarkable objects lately visited by the members of the institution of Mechanical Engineers were the great furnaces at Ferryhill, the largest, as our readers know, yet constructed. The pair, 27 ft. in diameter in the boshers, and 105 ft. high, have been successfully working for the last two or three years, no difficulty being found as to crushing the coke by the height of the columu of materials, nor as to raising the materials themselves by the hydraulic hoists, constructed by Sir William Armstrong and Co.; and at the same time the temperature of the gases at the tunnel head, or rather, under the bell, is, we understand, hardly 500 degrees. The stacks are not supplied with sufficient blast, but their make, as reported to us, is enormous. With an iron stone containing 37 per cent of iron, three casts are made every twenty-four hours, and the daily cast from each furnace is from 75 to 100 tons, or a maximum of 700 tons each per week. —*Engineering.*

Iron Analysis.—Gintl gives a very easy method of determining the impurities in cast iron. It is applied by him to the estimation of the sulphur contained in the iron; but, as will be seen, it is available for the separation and determination of most of the usual impurities. The iron is reduced to as minute a state of division as possible, and is then treated with a strong solution of perchloride of iron, as nearly neutral as possible. The mixture is kept heated for ten or twelve hours, at the end of which time almost all the iron will be found to have dissolved, leaving, as a residue, the carbon, sulphur, phosphorus and silicum, together with the little iron left undissolved. This residue has only to be well washed, oxidized and dissolved, and the sulphur estimated as sulphate of baryta. The exact plan directed by the author is to introduce the residue and filter into a porcelain crucible, having at the bottom three parts of nitrate of potash and one part of hydrate of potash; heat to fusion, dissolve and precipitate with chloride of barium. The phosphorus and silica will be contained in the same solution, and can be determined separately.—*Jour. Franklin Institute.*

An Alloy of Iron and Zinc.—It is a well-known fact that iron is dissolved by molten zinc, but nowhere is any definite alloy of these metals described, nor is it also stated how much iron is dissolved by zinc. Dr. Oudemans, Jr., obtained from analysis a piece of metal which had been formed in an iron vessel wherein zinc had been fused for several weeks continually; this metal was found deposited at the bottom of the vessel, and became an impediment to the melting operations in consequence of the relative infusibility of the alloy. In physical aspect this latter was of very much whiter color, and entirely different crystalline structure from zinc; the alloy dissolved very readily and briskly in dilute sulphuric or hydrochloric acid, and was found, on analysis to contain 4.6 per cent of iron. Taking for granted that this alloy is a definite compound of the constituent metals, its formula would be—FeZ_{36}(F=56 ; Zn32 75).—*Jour. Franklin Inst.*

Iron and Zinc.—It is a well known fact that iron is dissolved by molten zinc, but nowhere is any definite alloy of these metals described, nor yet is it stated how much iron is dissolved by zinc. Dr. Ondemans, jr., obtained for analysis a piece of alloy which had been formed in an iron vessel wherein zinc had been fused for several weeks continuously; this alloy was found deposited at the bottom of the vessel, and became an impediment to the melting operations, in consequence of its relative infusibility. In its physical aspect the alloy was of very much white color, and crystalline structure entirely different from zinc; the alloy dissolved very readily and briskly in dilute sulphuric or hydrochloric acid, and was found, on analysis, to contain 46 per cent of iron.—*Quarterly Journal of Science.*

Crystallization of Iron.—During an examination of the Heaton process for making steel at Langley Mill, Mr. Crookes has noticed a remarkable instance of the crystallization of iron. When the violeuce of the action between the molten iron and the nitrate of soda has subsided, the lower portion of the apparatus, called the converter, is detached, and after a few minutes the coutents are turned out on to the floor in the form of a porous mass of nearly three-fourths of a ton in weight. Upon examining portions of this metallic sponge, it is found to consist of a segregation of minute feathery crystals of iron, apparently built up of small cubes. The outlines of some of these are perfectly sharp, and their appearance, specially in the cavities, is very beautiful.—*Quarterly Journal of Science.*

Improved Blast Furnaces.—The Fraisans Ironworks, near Besançon, have recently received many improvements in the system of construction and in the working of the blast furnaces. The furnaces are 65 ft. high, and 11 ft. 6 in. diameter at the top; they are nearly cylindrical; the diameter is 13 ft. 2 in. only at 12 ft. over the ground. There are eight tuyeres around the furnaces, and the diameter is 11 ft. 6 in. to the level of the tuyere. Up to 12 ft. from the ground the wall of the furnace is made with hollow cast-iron plates inside, through which there is a constant flow of water; the lining of the furnace is made with a single row of fire-bricks, 4 in. thick; the upper part of the furnace is made of riveted sheet-iron; the fire-brick lining is also 4 in. thick, but there is a distance of 2 in. between the sheet-iron and the bricks, and a circulation of air prevents the overheating of these bricks. This arrangement admits of very quick construction, and the body of the masonry being very little it is easily dried; one of these furnaces was in working order three mouths after the beginning of its construction. The daily production of these furnaces is above forty-five tons of pig iron. The ore, which contains 40 per cent. or 45 per cent, of iron, is supplid by rail from a distance of eight miles; the coke comes by canal from St. Etienne, Montchanin, or Epinac—an average distance of eighty miles. The consumption of coke is 18 cwt. for one ton of pig iron. The ore is mixed with 30 per cent of puddling furnace slags; these slags are ground, and mixed with lime and manganese, and then converted into bricks, which are carefully dried and set with the ore in the blast furnace. The silicon of the slag unites itself with the lime, and the oxide of iron is reduced; the slag is prevented from smelting before this reduction. This system admits the introduction of slags in the blast furnace in a much larger proportion than usual. The pig iron seems to be produced at the price of about £2 12s. per ton, which is very low for a district so far from the collieries.—*The Engineer*.

Improvements at Creusot.—A new wrought-iron chimney has been recently erected at the Creusot Ironworks. It is 197 ft. high and 6 ft. 7 in. diameter. At the bottom the diameter is increased to 10 ft. by a curved base, which is fastened by vertical bolts to masonry work. The thickness of the sheet-iron is 3-32 in. at the top, and 7-16 in. at the bottom. There is an inside iron ladder. The weight of this chimney is forty tons; it has been riveted horizontally and lifted afterwards with a crane. Another one, 275 ft. high, will be soon erected, but by a different system; it will be riveted vertically, with an inside scaffolding. These chimneys are built for an extension of the Creusot Works, especially intended for steel-making. There will be eight Bessemer converters, where the cast-iron will be run direct from the blast furnace; there will be also many Martin's furnaces, and an extensive workshop for melting steel in crucibles, where it will be possible to melt together fifty tons of steel. All these new works are surrounded with great mystery, and the admission of visitors is rigorously prevented.

Steel Fire Boxes.—It is stated by the "Iron Age" that the Baldwin Locomotive Works recently ordered 125 tons of steel plates from a Philadelphia maker.

The Pencoyd Iron Works.—These works are located on the line of the Reading railway and Schuylkill canal, about six miles from the city of Philadelphia. The location is one that enables the proprietors, Messrs. A. & P. Roberts, to obtain coal from the Broad Top region, and pig iron from Schuylkill and Lehigh Valleys, at a minimum cost. The works were established in 1852, and the first order, for twelve hammered axles, was received and executed in December, 1852. Finding a number of the railways were using the rolled axle, most of which were imported at that day, the proprietors determined on the erection of a rolling mill, which was put in operation in the fall of 1854, since which the business has been steadily increasing, until it has reached a product of 30,000 axles a year; and they have earned a reputation for their axles, both rolled and hammered, that is second to none in the country.

These Works consume largely of scrap iron, all of which is thoroughly cleansed from dirt and rust by placing it in revolving cylinders, preparatory to piling and rolling. The rolled axles are further improved by having the journals hammered in; after the axle is made, the ends are placed in a heating furnace and brought to a white heat, and then placed under a heavy hammer; this serves to clean and condense the iron, giving a cleaner and better wearing surface.

They have lately engaged in the manufacture of Bessemer steel axles, and are now executing an order of some 200, for the Pennsylvania railway, under a guaranteed test of a drop 1649 pounds, falling 20 feet, the axle to stand five blows, reversing at each blow. The axles are made four feet longer than required in use, to give a trial piece. They are also making bridge bolts, piston rods, etc., of Bessemer steel, and lately rolled bridge bolts for the Philadelphia, Wilmington and Baltimore railway, of this steel, 35 feet long, $2\frac{1}{2}$ inches in diameter. In addition to the axle business, which is their speciality, they manufacture bar iron, bridge bolts, guaranteed to stand 60,000 pounds tensile strain to the square inch, and Pencoyd shafting.—*American Railway Times.*

Qualities of Steel.—Kirchweger gives the following review of various sensible qualities of the different sorts of steel and iron:

Cast-steel shows a fine-grained and most regular fracture, hardens by sudden cooling, contains from 1.5 to 1.75 per cent carbon, and possesses 183 lbs. absolute resistance per square millimeter.

Puddled cementation, or blister steeel, welds and hardens, contains from 0.66 to 0.49 per cent. of carbon; absolute tensile resistance 128–199 lbs.

Bessemer steel is fit for welding, hardens very little, is very flexible, fine-grained in the fracture like cast-steel, and contains from 0.51 to 0.65 per cent of carbon; absolute tensile resistance 111–150 lbs.

Fine-grained iron is fit for welding, shows a fine-grained fracture, does not harden, and contains from 0.51 to 0.65 per cent carbon; tensile resistance between 70 and 117 lbs.

Boiler-plate iron is fit for welding, does not harden, shows a fibrous harsh fracture, and contains between 0.50 and 0.65 per cent carbon; resistance 66 lbs.

These comparative statements must only be taken for what they are—mean deductions from German manufacture.

The Utilization of Blast-furnace Slag.—At the Cleveland Institute of Civil Engineers, Mr. Crossley has recently brought forward some interesting facts and suggestions with regard to the possible utilization of blast-furnace slag. Mr. Crossley states that blast-furnace slag is a compound containing an excess of lime; gray slag contains in 100 parts, and on an average:—silica 38.25, alumina 22.19, lime 31.56, magnesia 4.14, protoxide of iron 1.09, manganese a trace, sulphide of calcium 2.95; but its composition is not uniform, and differs according to circumstances. Several things can be done with slag, though its chemical composition would lead us to imagine that it is almost valueless. It can be converted into paving stones, it can be used to obtain sulphate of alumina, aluminate of soda, and pure silica for the manufacture of porcelain. The author makes known a plan of his own in which the slag, after being pulverized, is treated with hydro-chloric acid, which gives the silica in a gelatinous form whilst the alumina, lime, magnesia and iron are dissolved. The solution is evaporated to dryness, washed with water to dissolve the soluble salts, and the insoluble residue is treated with sulphuric acid, by which means sulphate of alumina is formed, the solution of which may be decanted off; the silica, after washing the water, is left in a pure state. The sulphate of alumina may either be evaporated to obtain the salt in a solid or dry state, or it may be directly used for the manufacture of alum. By this process they will give a product worth 3*l.* per ton, and another worth 7*l.* per ton. Every 100 tons of slag will yield 33 tons of pure silica and 147 tons of sulphate of alumina. In some districts certain of the rarer chemical substances are found in blast-furnace slag, and might be extracted as by-products and sold to the dealers in chemical curiosities.—*The Scientific Review.*

Analyses of Swedish Blister Steel.—Dr. David Forbes has examined cementation steel, manufactured at Sheffield of Swedish bar-iron, and found its constitution:

Carbon, in chemical combination	0.627
Carbon, graphitoid	0.102
Silicon	0.030
Phosphorus	0.000
Sulphur	0.005
Manganese	0.120
Iron	99.116
	100.00

Seyfert, McMannus & Co., proprietors of the Reading Iron Works, employ 2,000 men in their foundry, steam forge, rolling and nail mills, tube works, &c. The rolling mill has a capacity of 5,000 tons per annum; the tube mill about 10,000,000 feet of wrought iron gas, steam and water tubes, besides 3,000,000 feet of lap-welded boiler tubes; 350 tons of pig metal are produced daily, and about 5,000 tons of sheet iron annually. The wages amount to $70,000 per month.—*Iron Age.*

The Bethlehem Iron Company have a strong force at work putting up their new rolling mill in South Bethlehem, which, when finished, will be the largest mill of its kind in the United States. It is to be 400 feet wide by 900 feet long. They intend to manufacture all kinds of railroad iron, and also steel rails. Siemens furnaces will be used exclusively, for both puddling and heating.

ORDNANCE AND NAVAL NOTES.

Small-arm Powder.—The particular point to be attended to in comparing small-arm powders is, which gives the best target—that is, virtually, which is most uniform. A powder which gives the best target will, when tested by the Navez-Lewis electro-ballistic apparatus, be found also to show the greatest uniformity in the velocity imparted to the projectile.

One powder may surpass another, either in incorporation—that is, in the thoroughness with which the three ingredients have been worked together; or in physical qualities—the shape, density and hardness of the grains. Practically, all the best English powders, whether made by Government or by the private makers, are equal as to incorporation. No foreign powders can compete with them in this quality, as may be easily tested by flashing off a few samples of both on a glass plate. The specks of unburnt saltpeter and sulphur which all foreign powders leave on the plate show the imperfect manner in which they have been worked. This arises from the insufficient nature of the incorporating machinery in use abroad, where the powerful iron and stone mills now universally used in this country are unknown. An imperfectly incorporated powder would never shoot strongly or regularly, and would, moreover, foul the piece excessively. The conversion of the incorporated ingredients into grains is the part of the manufacture which most affects the shooting qualities of powder. The only way to effect this is to press the mixture into hard cakes in a hydraulic press, and then crush these into grains between toothed metal rollers. The density and hardness of the finished powders (most important features) depend entirely on the pressing process and on the state in which the mixed ingredients are before being submitted to it; and, although it is impossible to ensure uniformity of results with the present machinery, two powders may be made to agree tolerably closely in these particulars. The grains, after being freed from the dust generated in the granulating process, are glazed or polished by long continued friction together in revolving wooden barrels. If this process affects, to any very considerable extent, the shooting qualities of the powder, it is, probably, not so much by imparting a surface or glaze to the grains as by rubbing them down to a more uniform shape.

The extent to which a little variation in the sizes and shapes of the small black grains which constitute a charge of powder affects the shooting is very remarkable, as every grain takes a different time to burn in proportion to its size and shape. Supposing the density and hardness to be uniform, it follows that, if cartridges could be made up of grains all absolutely alike in these two particulars, absolute uniformity in shooting would be obtained. The delicate modes of proof which we possess afford conclusive evidence in support of this. A minute examination of the ordinary small-arm powder of the service—the "rifle fine grain" as it is called—will show that it is made up of grains which vary very considerably in size. It is, in fact, when finished, sifted out between sieves of twelve and twenty meshes to the inch; it must all pass through the former and be retained on the latter. If a quantity of this powder be taken and sifted on sieves of 12, 14, 16, 18 and 20 meshes to the inch respectively, and if cartridges be made up out of the several siftings and fired against others made up with the powder itself, the former, as a rule, will give very decidedly more uniform results than the latter, and the smaller the size of grain used the higher will be the velocity imparted to the bullet. * * * *

Unless some important alterations be made in the granulating machinery so as to enable it to crush up the pressed ingredients into more even sizes of grain, there is no possibility of obtaining quickly a large supply of powder of very even size. And if one size only be made at a time, it would cost as much for time and labor as treble the quantity containing greater varieties of size of grain. This is enough to account for the high prices such powders must always bear, without having recourse to the supposition that any one maker more than another possesses some important secret which enables him to turn out better powder. There is no article the good or bad qualities of which can be more easily detected, and nothing but an honest expenditure of capital, time and labor, can produce a good article. —*Army and Navy Gazette.*

PROOF OF GUNS.—Mr. Whitworth says of the late trial of the 9 in. Fraser gun, pronounced so wonderful by the British press, viz: firing 19 tons of powder and 124½ tons of shot in 1,114 rounds, that as more than half the rounds fired were with powder charges, only about one-half the most effective charge, and the remainder with three-quarters the charge, while all the shots fired were only two-thirds the best weight for that size of bore, I contend that it was no proper test of endurance, but sheer waste of ammunition.

Mr. Whitworth thus describes his own mode of proof:—It consists in preventing the shot from moving when the powder is ignited, the gases generated by the explosion escaping only through the touch-hole. About one-sixth of the regular powder charge fired in this way gives the same strain to the gun as a full charge fired in the ordinary manner. To prevent the movement of the shot, a screw is cut on the periphery of the gun at the muzzle, and on it is fitted a screwed cap having a solid end. The gun is loaded with a cartridge of the ordinary length, but containing one-sixth of the regular charge, and supported by tin discs in the center of the bore; a flat fronted shot, with tight wads to prevent any escape of gas, and a round steel bar reaching from the shot to the end of the bore, are then introduced, and the cap with the solid end screwed on. The gun is then ready for firing, after which my measuring instrument is introduced into the bore, and any enlargement to the 10-1000th of an inch in extent may be ascertained. If there be no enlargement, the powder charges may be gradually increased, until a slight enlargement has been produced. The real strength of each gun is thus positively ascertained, and this strength I would have recorded and stamped upon each gun. This would give confidence to the gunners, and would act as a check on those engaged in the manufacture. When the ultimate endurance of any particular kind of gun is thus to be ascertained, the regular powder charges, or any less quantity deemed desirable, may be used, the enlargements being recorded after each discharge. A 9-pounder bore gun made of my metal, but reduced 12 in. in diameter, has been so tested, and has had 18 full charges of 1½ lbs. fired from it. The expansion in the bore is now .1903 in., and that of the outside diameter is .0485 in.

THE FRENCH NAVY.—The "Revue Contemporaine" contains an article, by M. Amédée Marteau, on the origin and gradual introduction of armor-plated vessels into the French Navy. After recalling to mind the first attempt in that direction, during the Crimean war, when a few unwieldy iron-clad floating batteries silenced the fort of Kimburn, then the construction of the first armor-coated frigates in France, the Gloire, Invincible, Couronne and Normandie, the author adverts to the first voyage of an iron-clad across the Atlantic, performed in 1862, by the latter when sent over to Mexico with Admiral Jurien de la Gravière on board. It was found that her rolling was fearful, as had been predicted by the adversaries of the system, who reasoned on the principle that her armor would render her top heavy, which, according to theory, must cause that defect. It was in order to remedy it, that her altitude above the water-line was diminished, and her masts were lightened, on her being sent on an experimental trip to the Canaries, in 1863; but quite the contrary effect was produced. At Madeira, a consultation was held on board, which ended in a resolution to try whether increasing the weight above, and diminishing it below might not prove a corrective, in spite of theory; and so it was: about 200 tons of conical missiles were got out from the hold and piled on deck, and this actually diminished the rolling considerably. The old theory has since been proved erroneous by mathematical calculations founded on these experiments. The new principle was immediately carried into effect in the Magenta and Solferino, which received two tiers of batteries, whereby the upper weight was considerably increased, and the vessel greatly steadied. Four turret frigates, the Ocean, Marengo, Suffren and Friedland are now building, and will carry sixteen 11-inch guns. But besides these, a flotilla of corvettes is partly formed, and partly in course of execution. Instead of four turrets, like the frigates, they have two, and carry, moreover, four guns between decks. Each is armed with a spur, weighing twenty-two tons, and is propelled by a 450-horse engine, which, however, may, if necessary, increase its power to 1,800 or 2,000 horse.

THE NEW BRITISH RIFLE.—The 200 Martini-Henry rifles which are about to be issued to the troops for trial will, it is stated, be disposed of as follows: One hundred will be sent to India, to be divided among the three Presidencies; fifty will go to Canada, as the station which, as regards climatic conditions, stands in the most direct opposition to India; and the remainder will be issued to the troops at home. The arms will be fired as much as possible, moved from one station to the other, taken on the march, passed from regiment to regiment, and subjected to as many of the vicissitudes of actual service as can be imitated or produced in peace time. About a million rounds of ammunition will be manufactured for this trial; but we regret to hear that the strengthened or "bottle-necked" cartridge is not yet decided upon, and it will, therefore, be necessary to supply the long cartridge, which is not unlikely to prove somewhat weak on service. The "bottle-necked" or shortened cartridge will, doubtless, be preferred ultimately, and it is unfortunate that some of these cartridges, with arms to match, could not have been issued at the same time as the others for comparative trial.—*Engineering.*

Eads' Gun Carriage.—There is now in construction at Fort Hamilton, a carriage to be worked by compressed air, and it is thought, by engineers who have examined it, that it will prove a success. To secure solidity and durability, and also to provide a sufficient support for the gun and carriage, weighing together over 61 tons, a circular excavation 15 feet in depth was made, and upon the bottom a grillage of timbers, each 15 inches square, was constructed. Then six feet of earth, firmly packed, was placed upon and between the timbers forming the grillage, and upon top of the earth, about five feet in thickness, or 150 tons in weight of concrete was laid, and surmounting this is a granite cap or table weighing 42 tons. Sunken into the granite and fastened to it by ten bolts, $2\frac{1}{2}$ inches in diameter, and reaching up through from beneath the grillage, and ten bolts of the same diameter reaching through the granite only, is the bed plate, weighing four tons. Resting upon numerous small wheels which revolve upon a circular track in the center of the bed plate, is the gun carriage, an ordinary triangular-shaped affair substantially built. Projecting from the rear, and underneath the carriage, is an iron arm which is securely bolted to a piston rod working in a cylinder. The cylinder is filled with compressed air supplied from a hydraulic pump, worked by a small steam engine, the pressure in the cylinder being 400 pounds to the square inch. When the gun is fired the recoil is received in this cylinder, and upon the compressed air, by means of the piston rod connecting with the gun carriage. The pressure of the compressed air, it is expected, will check the recoil, and throw the gun forward to its place, or by the use of a lever it can be held back until it is loaded. Surrounding the gun, and with an inclination toward the muzzle, is a wrought-iron apron, upon the top of which is a track or groove, in which the balls or shells are placed, the inclination of the track forcing them around directly under the muzzle of the gun. At this point the ball drops upon a frame bolted to a piston rod working in a small cylinder. The piston rises, carrying the ball with it, until it is opposite the muzzle, when, by an ingenious arrangement, the frame holding the ball is tilted over, and the ball rolls into the gun. This cylinder is bolted to the gun carriage, and is, of course, always in position to raise the projectile. The gun being revolved, run forward, and the principal part of the loading done by the aid of compressed air, but little remains to be done by hand, and the inventor is confident that the gun can be loaded and fired six times a minute, or more than thirty times as fast as by the present mode. If the invention is a success, the advantages accruing from it will be inestimable in a military point of view, and the principle can be applied to ships-of-war, or, in fact, to any or all heavy guns in whatever position they may be placed. The carriage is being constructed upon the designs of Capt. Eads, under the immediate supervision of Mr. Wm. Lane, engineer in charge of Fort Hamilton, and he expects to have it ready for use within a week.—*Tribune.*

A New Explosive Material.—The following account of a new explosive material is abridged from the "Kölnische Zeitung," May 19th, which gives the "Militär-Wochen-Blatt" as its authority: "It is now some time since the proprietors of the Nora-Gyttorp Powder Mills obtained a patent in Sweden, for the discovery of the so-called 'ammonia powder,' a substance which has hitherto been only employed in a few mining districts, but which otherwise seems wholly unknown. Its explosive force may be compared to that of nitro-glycerine, and, consequently, far surpasses that of dynamite. It cannot be exploded by a flame or by sparks, and the explosion is effected by a heavy blow from a hammer. Blast holes loaded with this powder are exploded by means of a powerful cap, or, better, by means of a cartridge containing common powder, for this forms a more reliable exploder. One of the useful and important properties of this new powder is, that it does not require heating in cold weather, whilst nitro-glycerine and dynamite must first of all be warmed, and this has been the cause of many accidents." The same paper further adds: "According to information we have received, ammonia powder was discovered by the chemist, Norrbin." The German "Building News" contains extracts from a report of the Prussian architect, Steenke, who makes the following remarks upon the safety of ammonia powder: "Experiments were made by fastening a lamp to a pendulum, which was caused to oscillate; gunpowder, gun-cotton, nitro-glycerine, and dynamite, all took fire as the flame passed over them, but the ammonia powder did not begin to burn till it had been touched by the flame twenty times. In making experiments upon the force of the blow required to explode it, it was found that, with the apparatus employed, where the fall of a weight from 4 to 5 ft. would explode gunpowder, nitro-glycerine only required $1\frac{1}{2}$ to 2 ft., dynamite $2\frac{3}{4}$ to 3 ft. fall, whilst a fall from 12 to 15 ft. was necessary to cause the explosion of the ammonia powder."

Gun Cotton.—At the Cambridge meeting of the Association in 1862, a committee, consisting of representatives of the mechanical and chemical sections was appointed for the purpose of investigating the application of gun-cotton to warlike purposes. At the Newcastle meeting in the following year this committee presented their report. It was felt that a complete study of the subject demanded appliances which could be obtained only from our military resources, and at the Newcastle meeting a resolution was passed recommending the appointment of a royal commission. This recommendation was adopted, and, in 1864, a commission was appointed which was requested to report on the application of gun-cotton to civil as well as to naval and military purposes. The committee gave in their report last year, and that report, together with a more recent return relative to the application of gun-cotton to mining and quarrying operations, has just been printed for the House of Commons.

A substance of such comparatively recent introduction cannot be fairly compared with an explosive in the use of which we have the experience of centuries. Yet even with our present experience, there are some purposes for which gun-cotton can advantageously replace gunpowder, while its manufacture and storage can be effected with comparative safety, since it is in a wet state during the process of manufacture, and is not at all injured by being kept permanently in water, but merely requires to be dried for use. Even should it be required to store it in the dry state, it is doubtful whether, with the precautions indicated by the chemical investigations of Mr. Abel, any greater risk is incurred than in the case of gunpowder. In the blasting of hard rocks it is found to be highly efficient, while the remarkable results recently obtained by Mr. Abel leave no doubt of its value for explosions such as are frequently required in warfare. General Hay speaks highly of the promise of its value for small arms; but many more experiments are required, especially as a change in the arm and mode of ignition require a change in the construction of the cartridge. In heavy ordnance, the due control of the rapidity of combustion of the substance is a matter of greater difficulty; and though considerable progress has been made, much remains to be done before the three conditions of safety to the gun, high velocity of projection, and uniformity of result, are satisfactorily combined.—*Prof. Stokes, British Association.*

The Palliser Gun.—Some particulars are to hand relating to the practical working of a number of guns converted upon Major Palliser's system, and which will prove interesting to our readers. In 1866, eight cast-iron 24-pounder and 32-pounder smooth-bore guns were converted by Major Palliser into 56-pounder and 64-pounder rifled guns, with a view of ascertaining whether our large stock of cast-iron guns could be advantageously converted into rifled cannon. Of these eight experimental guns one was tested for endurance, by firing continuously, with shot of 64 lbs. weight, until it had completed 2,285 rounds, of which 2,170 were with 8 lbs. charge, eighty-eight with 14 lbs., two with 12 lbs., one with 10 lbs., and twenty-four with 16 lbs. and 86 lbs. shot. The power of endurance of the converted guns was thus thoroughly proven. Six of the remaining guns were issued for service to home and foreign stations, in order that the Royal Artillery might have an opportunity of practicing with them. The preliminary reports from these stations have now arrived, and are, on the whole, very satisfactory. The 64-pounder issued to Devenport has fired over 300 rounds, the gun is reported to be perfectly serviceable, and no complaints have been made of any difficulty in working. The Sheerness 56-pounder gun has fired 200 rounds, and the practice is reported as excessively accurate. The report from Gibraltar speaks in high terms of the accuracy of the 56-pounder issued to that station. The gun has fired 400 rounds, and is perfectly serviceable. The 56-pounder issued to Malta has fired 250 rounds. At Dover a 64-pounder has fired over 180 rounds with remarkable accuracy. The gun is spoken of as being, for handiness and fitness for rough work and exposure, in every way equal to the old 32-pounder. The 64-pounder on board the "Excellent" has fired over 480 rounds with great accuracy, the working of the gun carriage, &c., being in every way satisfactory. These reports are of much interest, proving, as they do, that the converted 64-pounder gun is fully equal to the more expensive wrought-iron gun of the same caliber.—*Mechanics' Magazine.*

Light Guns for India.—The Indian field equipment committee have recommended the adoption of the modified French rifling in place of the Woolwich rifling originally proposed. It will be recollected that two riflings were in competition—the first being a modification of the French groove suggested by Colonel H. Maxwell, Royal Artillery, superintendent of the gun factory at Cossipore; the other that form of groove known as the "Woolwich." The French groove gave slightly better accuracy and a somewhat lower trajectory, but it was thought that the wear of the guns, after continued firing, was somewhat greater with the French rifling. And as the question of wear is one of importance, the committee, in their preliminary report, recommended the Woolwich system; but when the two guns came to be exactly measured to the thousandth of an inch, it was found that the modified French groove had really worn less than the Woolwich groove, and the guns will, therefore, be rifled in accordance with this experience. The question of ammunition is still in abeyance, awaiting the report of the Dartmoor Shrapnel *versus* Segment Committee, but as that report was, we believe, signed on Saturday, the uncertainty on this point cannot be of much longer duration.—*Engineering.*

New British Ironclads.—The following armor-clad ships are now under construction for the Admiralty, either at the royal dockyards or private shipbuilding establishments. They are said to be in such a forward state that they will be completed during the present or early in the ensuing year:—The Sultan, 12, 5,226 tons, 1200 horse power, and the Glatton, 2, 2,709 tons, 500 horse power, double screw turret ship, building at Chatham dockyard; the Iron Duke, 14, 3,774 tons, 800 horse power, double screw, building at Pembroke dockyard; the Swiftsure, 14, 3,893 tons, 800 horse power and the Triumph, 14, 3,893 tons, 800 horse power, building by the Palmer Shipbuilding Company at Jarrow-upon-Tyne; the Hotspur, 2, 2,637 tons, 600 horse power, armor-plated ram, building at the yard of Messrs. Napier & Sons, Glasgow; and the Vanguard, 14, 3,774 tons, 800 horse power, building by Messrs. Laird Brothers, Birkenhead. In addition to the above, the Abyssinia, 4, 1,854 tons, 200 horse power, and the Magdala, 4, 2,107 tons, 250 horse power, double screw iron armor-plated turret ships, are building for the defense of Bombay, the former by Messrs. Dudgeon, at Poplar, and the latter by the Thames Iron Shipbuilding Company at Blackwall. As soon as one of the building slips becomes vacant at Chatham dockyard, a new armor-plated ram, to be named the Rupert, of 3,159 tons, and 700 horse power, is to be commenced at that establishment.—A new armor-plated turret ship, the Devastation, of 4,406 tons, and 800 horse power, from the designs of Mr. E. J. Reed, C. B., has been recently commenced at Portsmouth dockyard.

Submarine Steamship.—The accounts given of the new submarine steamship invented by Otto Vogel sound fabulous, and yet the Berlin *Börsenzeitung* asserts that the Prussian Admiralty has approved of the plans submitted to them for inspection. The vessel, covered with strong plating, is entirely below the surface of the sea, with the exception of the deck, which is surmounted by a vaulted iron roof of immense strength. Beneath this covering heavy guns are placed, so that the whole greatly resembles a first-rate ironclad. It is said, however, that besides all the advantages of such men-of-war, the new ship may be entirely submerged, and in this position is so completely under command that it can outweather a storm or attack an enemy with submarine cannon and torpedoes. Vogel is now engaged in constructing a large model twenty-four feet in length which will soon be finished.

Gen. J. G. Foster, U. S. Engineer, has devised a new and ingenious counterpoise gun carriage.

The following statement of the nominal strength of the armies of Continental Europe was not long since given by Baron Kuhn in the Austro-Hungarian Parliament:

France.	
Army	800,000
Mobile National Guard	550,000
Total	1,350,000
North German Bund.	
Standing army	843,394
Landwehr	185,552
Total	1,028,946
South Germany.	
Standing army	156,760
Landwehr	43,411
Total	200,171
North and South Germany together.	
Total	1,229,117
Austro-Hungarian Monarchy.	
Regular forces including navy and reserves	800,000
Border troops	53,000
Landwehr	200,000
Total	1,053,000
Russia.	
Field army, including army of the Caucasus	827,350
Local forces	410,427
Irregulars	229,223
Total	1,467,000
Italy.	
Army	348,461
Mobile National Guard, including Venetia,	132,300
Total	480,761

Velocity of Shot in Guns.—A series of experiments has been carried on during the last few days at the proof butt, Royal Arsenal, Woolwich, with instruments invented by Captain Noble, late of the Royal Artillery, and now one of the firm of Sir William Armstrong & Co., at Elswick, to measure the velocity of a shot while on passage in the bore of a gun when fired, and also to test the strength of gunpowder. The results of the experiments are not yet made known, but it is anticipated that they will materially alter the data upon which theoretical calculations are made in gunnery.

Improved Cartridges.—A great improvement has been effected in breech-loading cartridges, by the Colt Firearms Company, by which the cartridge case can be reloaded and capped after firing, thus utilizing the same case a number of times. At the Frankford Arsenal the machinery for making the cases has been so much improved as to rival, in precision and automatic character, the machinery of the pin factory, or the mint, besides greatly reducing the cost.

RAILWAY NOTES.

Uniformity of Design and Style in Machinery of the Pennsylvania Railway.—This is now the inflexible rule in every department and class of equipment and manufacture. The reform in this respect, begun ten years since in the car department, now extends to, and is very nearly realized to all the departments of the road. The end arrived at was, as then explained, "to get our entire equipment in each class uniform;" and what particularly commended it was, that it would dispense with a superfluous variety of patterns and duplicate work on hand for repairs. A larger view of late has presented itself, expressed by the superintendent of motive power and machinery, in his report for 1868, who says that its importance, "both as a measure of economy and increased efficiency cannot be too highly estimated; for, with such a system only can the cost of repairs of locomotives and proportions of engines out of service be reduced to a minimum." The superintendent of motive power and machinery is assisted by a mechanical engineer, in charge of the drafting room, after whose designs all work is made; and gauges and templets are placed in the hands of all manufacturers for the company, with drawings of every portion, even to the seats for firemen and engineers in locomotives. As old stock wears out, it is cut up; and the numbers re-appear on "standard" engines and cars of uniform pattern throughout. No deviation is permitted, at any one's will or caprice; all changes must be adopted generally. The system is not a novel one; it is only peculiar to the road in the extent of its application. When the new car shops are completed, the company will manufacture all its own cars; and the time is not distant when it will replace all failing engines, and make all necessary additions to motive power, after a system equally comprehensive. Indeed, it is calculated that in five years, instead of the *forty* different classes of engines now in use (456 at this writing; additions every week), there will be but *three* main classes—standard 8-wheel passenger, standard 10-wheel freight, and standard shifting.—Each of the first two classes will have a "modification," the difference, however, consisting only in the diameter of the driving-wheel and the size of the boiler. An obvious result of the system will be the fact that many of the most important pieces of car or engine, being common to their class, will be *interchangeable*—in locomotives, for example, among castings, the driving-boxes, eccentrics, eccentric straps, etc., etc. The standard locomotive of the road is no less admirably adapted to its work and condition in style than in construction. Devoid of all the brass ornaments with which with superfluous outlay it is customary to overload engines; painted a plain black, with number in gilt and a few neat gilt traceries, it is easily kept clean and its entire look is in keeping with the character of its work. The engineers who at first parted reluctantly with the brass and the fancy painting would not now have them back. Their mistresses are admired not for adventitious charms, but for unpretentious, solid worth; for the relations "she" sustains to her lord and master are by no means without the refinements of sentiment and affection.—*Chicago Railway Rev.*

The Projected Tunnel Railway Under the Mersey to connect Birkenhead with Liverpool, for which powers were taken in a bill this session has been abandoned for the present.

THE MISSISSIPPI BRIDGE AT ST. LOUIS.—Work on the Mississippi bridge at St. Louis is being rapidly pushed forward. The shore pier on the St. Louis side has been completed to a point above low water mark, and the dredge boats are now employed in preparing for the sinking of a caisson for the second pier, which will be located about three or four hundred feet from the shore. The bed rock has been sounded. In order to hasten the completion of the bridge, a large body of workmen is engaged on the Illinois side, digging for the location of the final pier, and within two or three weeks the second pier in the water and the fourth pier on the Illinois side will be under way. The most difficult pier to construct is the third, near the center of the stream, owing to the rapidity of the under current and the sloping character of the bed rock. Engineering skill will, however, overcome all these obstacles, and as soon as the second pier is under headway the caisson will be sunk for the central one. The levee for several squares is covered with stone, brick and timber, which are being prepared for their respective positions. The estimated final cost of the structure is $7,000,000, $4,000,000 of which have already been raised. As the work progresses, there is no doubt but the Legislature, city council and county court, will render sufficient aid to complete the affair at an early day. The rapid currents, quicksand bottom and other difficulties, incidental to spanning a great stream like the Mississippi, will necessarily prolong the work, but that within three years at the furthest the bridge will be duly inaugurated, there can be but little doubt. Capt. Eads, the chief engineer, is laboring with enthusiasm and energy.—While in Europe he visited all the bridges of note, and secured translations of the reports of various civil engineers on the subject of bridge building, with a view to employing in the construction of the bridge the most approved plans, so as to secure a work that will not only be a model of beauty, as far as engineering skill is concerned, but durable as well. Associated with him is Henry Flad, a gentleman who ranks deservedly high among practical and scientific engineers. Both are confident of completing the bridge in three years at the longest, and even talk of two years as the most probable time. The work of tunneling Washington ave., St. Louis, will not prove as difficult a task as many suppose, and it is believed that it can be accomplished without disturbing either the sewer, water, or gas mains. Should this operation, however, prove too hazardous, then an elevated railway will be constructed. In either event the road will terminate in a grand union depot somewhere near Fourteenth street, forming a direct connection with the Pacific and other roads.—*St. Louis Times.*

THE BOILER WATERS OF THE PACIFIC RAILROAD.—There are very few railroads which are so located that good, fresh water for making steam is accessible. In the course of the long stretch of the Pacific Railroad, all the varieties of water which are annoying to engineers have been met with, and there is little doubt that the experience with these waters will prove of great value to the world. The table herewith presented exhibits the saline composition of the water at nine successive locomotive stations on the Union Pacific Railroad, the stations being from ten to fifteen miles apart. The analyses were made at the editor's laboratory, and are as complete as the small quantity of material used in the work would allow. It was impracticable to determine the contents of gases and organic matter. An examination under more favorable cricumstances will shortly be made, and it is confidently expected that in some of these waters a notable amount of the rare alkali metals may be found. The names at the top of the table designate the stations as represented on the railroad time-table.—*Chemical News.*

LIGHT ROLLING STOCK.—It has now been indisputably established that it is possible to construct a combined engine and carriage capable of accommodating 66 passengers, of both classes, the whole weight of which, fully loaded, shall not exceed, if indeed it do not fall short of 20 tons, while the adhesion weight is nearly half as much, or ten tons, and the average steam tractive force at least half a ton. The resistance of such a carriage at 20 miles an hour upon a level, would not exceed 300 or 400 lbs., nor, upon a gradient of 1 in 60, more than from 1,050 lbs. to 1,150 lbs., the whole actual work done being, say, 25 horse-power in one case and 75 in the other, or, supposing the speed on the gradient to be diminished to 17 miles an hour, to but 50 horse-power. The carriage is not one of the omnibus kind, but has seven compartments and guard's van, in all respects in conformity with the standard rolling stock of English lines. The weight per wheel being in no case greater than 2¼ tons, lines of corresponding lightness would serve as well as heavy lines now serve for heavy engines, loaded as they are to from five, six, seven, and even eight tons upon each driving wheel. If even half filled with passengers, such a carriage at ordinary fares would earn about 5s. per mile, and, if filled, of course, twice as much. The whole cost of working would certainly be small. When working upon moderately easy gradients, the consumption of coal would run but from 6 lbs. to 8 lbs. per mile, the wages of driver, stoker and guard, making 100 miles a day, to but 1¾d. per mile, and repairs to probably less than a pound a day, or 2¼d. per mile, these respective expenses being thus only 5d., or say, 6d. per mile, including all train charges. Permanent way, station expenses, and general charges might carry the whole to 1s. or 1s. 3d.; but even at twice the last named cost there would be a high proportion of profit on the work.

The motion of the carriage is easier than that of an ordinary train, the total wheel base being so much longer and yet so much easier from being formed upon swivelling bogies. It is almost impossible to imagine that if branch line and other short traffic passengers were allowed to make use of this carriage, they would not universally pronounce in its favor. Mr. Fairlie, the designer, having worked out his system upon the great scale, and with the most perfect success, as the experiments at Hatcham have abundantly shown, is not only to be congratulated, but is entitled also to the warmest thanks of the whole railway body politic.—*Engineering.*

Oscillation of Railway Trains.—Sir Charles Fox says in the "Times": The oscillation of railway trains, more especially at high velocities, producing what is ordinarily called "gauge concussion," is a very serious source of wear to the permanent way and rolling stock of railways, and, as a consequence, of great expense, to say nothing of the discomfort it occasions to passengers, and is, in my opinion, caused in very great measure by the use of wheels, the tires of which are portions of cones instead of cylinders.

If the English engineers would use the swing beam on their railway vehicles, they would be much less troubled from this cause.—*Ed. V. N. M.*

The Mont Cenis Tunnel.—The underground works of Mont Cenis are carried on with increasing spirit and energy. The opening of the great tunnel for the locomotive before July, 1871, is confidently predicted. The Italian minister of public works is hastening the construction of the railway from Susa to Bardonnêche, the southern opening of the tunnel; a guaranty, it is understood, being given that the grand opening will be completed, and the whole properly walled and strengthened by the time this railway is finished. The French government has given similar pledges as to the northern opening at Modane.

Railway Casualties in 1868.—The complete official tale of casualties to human life and limb on all the railways of the United Kingdom, during the twelve months ending with December last, is 212 killed and 600 injured. But among the killed eight suicides are counted for which the railways cannot be deemed responsible—unless, indeed, the eight unfortunates were shareholders. Making this deduction, we have 204 deaths. This, however, is under the mark, but how much under the return of the Board of Trade offers no means of estimating; it tells us only that the statement of "accidents to servants of companies or of contractors cannot be looked upon as complete, as many railway companies (not being required by law) do not report to the Board of Trade every accident which may have occurred to this class of persons." Nearly all the recorded injuries and about two-thirds of the recorded deaths fall under, with reference to the sufferers, two broad and opposite categories—accidents from causes over which the sufferers had no control, and accidents from causes originating in the misconduct or carelessness of the sufferers. The other deaths, about one-third of the whole, are classed without specific regard to these conditions.—*Engineering.*

The Thames Tunnel, which opened on the 2d of August, 1843, was closed in July last, having been a public footway for a period of twenty-six years, less thirteen days. It has been purchased for £200,000 (one-third of its cost) by the East London Railway Company, which line will be completed, as far as Wapping, in a short time. The new Thames Subway from Tower-hill to Bermondsey (Mr. Barlow's scheme), commenced on 16th of February of the present year, is proceeding very rapidly, and, if all goes well, will be opened for traffic in three months time. Its cost will be under £20,000. The works of the old Thames tunnel were commenced in 1825. Physical and financial difficulties delayed the opening for eighteen years.

The Dusseldorf Bridge.—The great railway bridge over the Rhine, near the village of Hamm, a little above Dusseldorf, is progressing rapidly, and will probably be completed before the end of November. The bridge is to consist of four arches, the upper part of which will be made of iron. The iron work of each arch will weigh 14,000 centners. The bridge is united to the main line on the left bank by a viaduct consisting of fifteen stone arches, but this viaduct does not immediately join the bridge; it is separated from it by a revolving drawbridge, so that the line can be rendered impassable at any moment. On the right bank a fort is being built which will command the whole bridge.

A Rapid Change of Gauge.—In Missouri, last month, the Missouri Pacific Railway, a road nearly 200 miles long, changed its line from the broad to the narrow gauge. Nearly 1,400 men were engaged in the work, and they labored with such celerity that the task was accomplished in twelve hours, and without interrupting the business of the road.

Boutet's Bridge.—A site for the erection of the model of the railway bridge from Calais to Dover, designed by M. Boutet, has been granted, at the Government marble depot, Paris, by the Emperor's minister of the imperial household.

NEW BOOKS.

Machinery and Processes of the Industrial Arts, and Apparatus of the Exact Sciences. By Frederick A. P. Barnard, LL.D., U. States Commissioner, Paris Universal Exposition, 1867. Washington: Government Printing Office, 1869. 8vo, pp. 669. For sale by D. Van Nostrand, 23 Murray street, New York.

This is an extremely valuable memoir upon a great number of important topics connected with the Industrial Arts and the applications of mechanical aud physical principles, as these were illustrated in the French Exhibition of 1867. These are considered iu a systematic and exhaustive manner, in fourteen chapters, of which the general headings are: I. The relation of invention to industrial progress, pp. 1–25; II. Motors, pp. 25–127; III. Transmissiou of force, pp. 128–150; IV. Accumulation of force, pp. 151–161; V. Measure of force, pp. 162–168; VI. Direct applications of force, pp. 169–218; VII. Meters for liquids and gas; Boiler feeders, pp. 219–236; VIII. Machines and mechanical apparatus designed for special purposes, pp. 237–280; IX. Processes and Products, pp. 281–332; X. Diving and Respiratory apparatus, pp. 332–346; XI. Improvements in the application of cold, pp. 346–360; XII. Artificial production of cold, pp. 361–402; XIII. Light-house illumination, pp. 403–416; XV. Printing and the graphic arts, pp. 417–468. Under each of these general heads we find grouped a great number of most interesting and important matters, about many of which it is impossible to find elsewhere, if at all, so clear and exact statements. The mere enumeration of the topics thus discussed would fill several pages of this Journal.

The just claims of American skill and science are fully stated, with occasional reclamations, among which we are glad to find under chapter XII, a full recognition of Prof. Alexander C. Twining's American Ice Machiue of 1850, which is unquestionably the progenitor of all similar machines, and which has been most shamelessly pirated and appropriated by European inventors. In concluding his account of Prof. Twining's apparatus, Dr. Barnard adds: "It cannot be too much regretted that an invention of so much merit and importance, and of which the souuduess and commercial value had been so fully demonstrated, both theoretically aud experimentally, should, through the apathy or timidity of capitalists, have been permitted to be neglected in the country in which it originated, till foreign enterprise had seized upon it, and developed it into a great industry."

This Report is illustrated by well-executed wood cuts of the most important forms of apparatus discovered, 154 in number, and is correctly and handsomely printed, under the supervision of Prof. W. P. Blake, charged with editing the Reports of the United States Commissioners of the Paris Exposition of 1867.—*Am. Journal of Science and Art.*

Submarine Warfare. By Lieut. Commander Barnes, U. S. N. D. Van Nostraud, 23 Murray street, New York. 1869.

This is an important book to military men, and consists of an examination of the various offensive and defensive engines that have been contrived for submarine hostilities, including a discussion of the torpedo system, its effects upon iron-clad ship systems, and its probable influence upon future naval wars. Plates of a valuable character accompany the treatise, which affords a useful history of the momentous subject it discusses. Beginning with David Bushnell, who was born in Connecticut in 1742, and was the first inventor of torpedoes, the narrative is brought down to our own day and includes those most famous practical epochs of submarine operations, the Crimean war and our own late struggle. The contrivances of Fulton, and his negotiations concerning them with the French and English governments, are described, as well as the later experiments of Colonel Colt and his cognate proposals to the authorities at Washington. The author regards the Southern States as the first power to introduce a regular system of torpedo warfare. It is, however, certain that the Russians used torpedoes, and even electricity as applied to them, for defending their harbors against the English and French. Fulton thought of this application of electricity, but gave it up as impracticable. The nearest approach to a complete torpedo-boat, in the opinion of the author, is the Spuyten Duyvil, built by Messrs. Wood and Lay, U. S. N. This vessel was not built in season to test her powers during our late war; but Captain Barnes thinks her the most formidable engine of destruction for naval warfare now afloat. A great deal of useful information is collected in his pages, especially concerning the inventions of Scholl and Verdue, and of Jones' and Hunt's batteries, as well as of other similar machines, and the use in submarine operations of gun cottou and nitro-glycerine.—*New York Times.*

A Short Course in Qualitative Analyses, with the New Notation. By J. M. Crafts. Professor of General Chemistry in the Cornell University. New York: John Wiley & Son. 1869.

Familiar with, and rightly appreciating the wants of students, Professor Crafts has prepared a manual as excelleut in design as able in execution. It goes over the whole field that a student would be likely to work in, in a condensed, yet eminently comprehensive and lucid manner. It gives full instruction in manipulation, explicit directions for conducting the various methods of testing and accurate accounts of the operation of the usual re-agents, together with the behavior of the various classes of substances in their presence. The general arrangement of the subject is the best, perhaps, that could be desired for the special aim in view; the divisions are natural; copious references, back and forth, among the different analyses, afford material assistance; while the letter-press itself, with its conspicuous headiugs, is called in to aid the student's progress. The very full tables, at the end, have all the force of diagramatic illustrations. We need scarcely add that the classification, nomenclature and notation are in accordance with latest researches in chemical philosophy. So very convenient, useful and trustworthy a book cannot fail to take and maintain the place it was intended for—at the elbow of the student working in the laboratory. We commend it to the favorable consideration of those engaged in teaching this branch of the science.—*New York Times.*

Bulletin of the National Association of Wool Manufacturers. Boston: Office, 11 Pemberton square.

The Locomotive Engineers' Monthly Journal. August.

A Manual of Machinery and Millwork. By William J. Macquorn Rankine, C.E., F.R.S., &c. London: Griffin & Co. 1869.

This in an entirely new work of Dr. Rankine's, the Regius Professor of Civil Engineering and Mechanics in Glasgow University.

The book is divided into three parts. The first treats of the Geometry of Machinery; the second, of the Dynamics of Machinery; and the third, of the Materials, Strength and Construction of Machinery. Under the head of the Geometry of Machinery machines are considered with reference to the comparative motions only of their moving parts; and rules are given for designing and arranging those parts so as to produce any given comparative motion.

Several problems in mechanism are solved by methods which appear not to have hitherto been published, and which possess advantages in point of ease or of accuracy. Such are those regarding the drawing of rolling curves, and of some kinds of cams; the construction of the figures of teeth of skew-bevel wheels, and of threads of gearing-screws, by the help of the normal section; and some improvements in the details of processes for designing intermittent gear, link motions aad parallel motions.

Under the head of the Dynamics of Machinery, are considered the forces exerted and the work done in machines; the means of measuring those quantities by indicators and dynamometers; of determining and balancing the reactions of moving masses in machines, and of regulating work and speed; and the efficiency, or proportion in which the useful work is less than the total work, in the different sorts of moving pieces, and their various combinations.

Under the head of the Materials, Strength and Construction of Machinery are considered; first, the properties of various materials, as affecting their treatment and use in the construction of machines; secondly, the general principles of the strength of materials; thirdly, the special application of those principles to questions relating to the strength and the construction of various parts of machines; and fourthly, the principles of the action of cutting tools.

The work is illustrated with numerous diagrams. We need scarcely say that any work of Professor Rankine's on a subject such as this cannot but be of great practical value. We have here simply to draw the attention of readers interested in machinery and millwork to its publication.—*The Builder.*

The Metallurgy of Iron and Steel, theoretical and practical, in all its branches, with special reference to American materials and processes. By H. S. Osborn, LL.D., Professor of Mining and Metallurgy in Lafayette College, Easton, Pa., with 230 engravings on wood and 6 folding plates. Philadelphia: Henry Carey Baird, 1869. For sale by Van Nostrand, 23 Murray street, New York.

This voluminous and extensively illustrated work is peculiarly valuable to American readers from the fact that the American practice is so largely described and illustrated. We have heretofore had no book on iron and steel, to any large extent drawn from home sources. While we can now confidently recommend this work to our iron makers, both scientific and practical, we must defer a more extended notice of it until another issue.

Transactions of the Institution of Naval Architects. Vol. ix, 1868, 4to., plates. Published at the Institution Rooms, 9 Adelphi Terrace, London.

This last volume is as good as its predecessors; perhaps, in one or two papers, better than some of the eight volumes before it.

There is one rather formidable evil that besets the character of a large proportion of the papers brought to the annual meeting of this Institution. It is that they are too much hobbies, trotted out by their authors for very practical purposes, no doubt, but these having very often a basis in gold only, the papers are apt to be exaggerative or one-sided; and the politeness of discussions, in which, probably, friends manage to take a prominent part, do not always counteract too favorable statements, much less expose quackery.

There are some papers to which this applies in this present volume—we will not risk the odium of specifying them; but, except in the case of two, we really do not see that any very decisive corrective was even attempted to be applied to statements which, left unchallenged, must lead people astray. There are nineteen papers altogether in the volume; the most ponderous—and, shall we say, puffy?—being that upon the well-worn "turret and tripod systems," and that scientifically the most able and important, being the last in the volume, by Prof. Rankine, "On the waves which travel along with ships." The doubts thrown upon Mr. Saxby's magnetic methods of detecting internal defects in iron, seem to be strengthened by the fact that, after more than a year has since elapsed, we hear no more about it. M. Rochussen's paper on the Treatment of Steel Plates is valuable and worthy of reference, notwithstanding that it contains (p. 8) one astonishing statement, viz: "as the mere cost of *melting* crucible steel, both in England and Prussia, is £9 per ton," &c. We had supposed that M. Siemens undertakes to melt cast-steel in crucibles at a total cost of under £1 per ton.

Were more and abler men of applied science to preside as chairmen at these meetings in place of ancient admirals and lords, the character of the papers would prove higher, and doubtful statements would be more effectually exposed.—*The Practical Mechanic's Journal.*

Scientific Studies, or Practical in Contrast with Chimerical Pursuits. Two popular lectures. By H. Dircks, C.E. Reprinted. Small 8vo. Spon, London, 1869. For sale by Van Nostrand.

In the first of the two of these popular lectures, Mr. Dircks returns to his first biographical love, and the subject of his previous larger and faithfully written biographies, viz: the "Life of the Marquis of Worcester," of 1865, and "Worcesteriana," of pleasant reading and contain some of the biographi-1866. These lectures, slight as they are, form very cal and historical cream of the larger life of the celebrated and wonderful marquis.

It is peculiarly fitting at this time, when another ignorant and self-sufficient parliamentary onslaught has been just made again upon the patent laws, that we should draw attention to Mr. Dircks' work first above given in title. Without venturing to affirm that we can agree in all the author's views as to the rights and wrongs of inventors, we may say that his views are generally full of good sense and clear thought, and that he individually and practically comprehends what he is writing about, when treating of discovery, invention and the proper and improper bearings of the existing patent law upon these. Nothing can better show the real incapacity of such legislators, as the openers of the late debate on the abolition of the patent laws, to deal with the subject, than their confusion of thought as to any distinction between discovery and invention; a confusion, however, from which many inventors' and patentees' minds are not exempt, but which Mr. Dircks labors to clear away. We commend this volume to all interested in patent-law reform, which is urgently needed, and which should be initiated by an effective Royal commission of enquiry commanded to *hear all* pertinent evidence brought before it, and not contrive merely to hear such as shall suit the foregone views of the commissioners, as before now has happened.—*The Practical Mechanic's Journal.*

Practical Mining, fully and familiarly described. By George Rickard. Small 8vo. E. Wilson, Royal Exchange, London, 1869. For sale by Van Nostrand.

This little closely-printed volume, which is pregnantly full of matter, does not belie its title; it is mining, limiting that to British metal-mining, fully and familiarly described, and by a man who obviously has had large experience.

It is, no doubt, impossible to condense into a thin volume of this size, by any process of close type and narrow margins, the whole that can or ought to be said upon so large and so varied a subject, on which much more might be written in the same homely and sensible view as this is characterized by.

But the information given is clear, good and practical, and we do not know a better elementary work to be put into the hands of a lad who has already mastered his schooling and is intended to become a miner; it will at least give him a good panoramic view of what he will be engaged in, and what sort of knowledge he must acquire to succeed as one of that specialized class of engineers called in Cornwall "mine captains."—*Practical Mechanics' Journal.*

Die Hauptheile der Locomotiv-Dampfmaschinen, &c. Bearbt. v. C. Schepp, Civilingenieur, Heidelberg, 1869. 1 vol. 8vo.

In the first part of this work the author clears the table, so to say, by a didactic and critical survey of all the different classes and constructions of locomotives which have got into established use. In the second part he proceeds to construction rules, and deduces *ab origine* the proportions, &c., of all the important parts, including some of the most recent German modifications and improvements of valve gear. It is a very useful book, to the reader of German, for the purpose proposed by the author, "self-study;" the best education that mechanic or any other adult man can ever receive—that which he gives himself; the only one that leaves no fortresses of ignorance in the rear, as all pupil-teaching often does, and as "cram" is sure to do.

Herr Schepp's atlas of plates are excellent and clear engravings, and valuable to the practical locomotive builder, all the necessary dimensions being given in figures, and a special system of cross-lining, now commonly accepted in Germany, is adopted, by which the constructive material of every part is obvious to the eye without the aid of coloring.—*Practical Mechanics Journal.*

Dictionary of Scientific Terms. By P. Austin Nuttall, LL.D. Strahan & Co., 1869.—For sale by Van Nostrand.

At a time when scientific and technical education is so much needed, the issue of a dictionary of terms in use in the practical sciences is timely, and cannot but be useful; more especially a good one, as this seems to be; although, no doubt, within the limits of it there are not a few omissions. Nevertheless, great pains seem to have been taken to render it as complete as possible, considering these limits. The work is preceded by a useful introduction to the classification and study of the sciences.

The Painters' Magazine. Cincinnati: J. Sonnendecker & Co., Publishers, 178 Elm street.

An excellent monthly, containing instruction in the various styles and branches of painting, and also information on the nature and composition of paints.

Inventors and Inventions, etc. In three parts: the Philosophy of Invention; the Rights and Wrongs of Inventors; and Early Inventors' Inventories of Secret Inventions. By H. Dircks, C.E. 8vo. Spon, London, 1867. For sale by Van Nostrand.

MISCELLANEOUS.

Enameling Iron with Glass.—Among the most interesting and beautiful processes of Birmingham industry must certainly be reckoned that of enameling iron with glass, by the patented method of Charles Henry Paris, of France, which was first introduced into this country, A. D. 1850, by Messrs. Selby and Johns, in conjunction with P. F. Griffiths and Co. The enamel is a hard siliceous glaze or covering, formed upon surfaces of wrought or cast iron, so as effectually to prevent any oxidation of the metal. According to a well-informed Birmingham manufacturer it transpires that sea-water, salts, and acids, produce no effect upon it. The process was first applied to the coating of culinary articles, such as saucepans, frying-pans, baking dishes, &c. It is now applied to wash-hand basins, meat dishes, tea-cups and saucers, dinner plates, &c. These articles, owing to their cleanliness and durability, command a large sale in this country. By far the greater part, however, are manufactured for use on board ship, or for the foreign or colonial market. A fall or blow may cause the enamel to chip, but the articles themselves are practically indestructible—a most important consideration where the replacement or breakage is difficult or expensive. Pipes for gas and water service have by this process been enameled to some considerable extent. Upon the introduction of this enameled ware it was usual to coat the articles of a grey color, and owing to their dull appearance the demand for them was somewhat circumscribed. Shortly after the white enamel was introduced with success, as being purer and cleaner in appearance. The printing of the enameled ware succeeded, and soon after Mr. Benjamin Baugh extended considerably the production by introducing enameled iron for door numbers, wagon plates, insurance plates, mill plates, sign, street, and index plates, show cards, door plates, station name plates, gradient plates, &c. By a later improvement elaborate designs are transferred in enameled colors to the surface of the plates, and subsequently burnt in a furnace, thus rendering them proof against atmospheric influence. Finger plates for doors have been manufactured on this principle with marked success, classic figures having been introduced, or sacred imagery, well according with the *Serrure de Tabernacle*. Another feature in the recent improvements is the imitation of engraved zinc plates with remarkable exactness. Enamel has been applied also with marked success to corrugated iron sheets for roofing and small buildings (a *chef d'œuvre* of Wolverhampton product), a purpose to which its capability of resisting the action of the atmosphere adapts it to a remarkable degree. There is little doubt that much greater extension of this and kindred branches of industry is in store.—*Cor. Engineer.*

VELOCIPEDE TRACTION.—A correspondent of "Engineering" says of the bicycle:

Merely looked on as a graceful scientific toy, I think the instrument worthy of consideration, and am sanguine of its being made use of for purposes of travel. If you will grant me the space, I would ask your insertion of the following data from Morin's experiments on traction, and Weisbach's calculations of the work performed by a man walking, and by comparison find the economy in bicycle riding.

Extracts from Morin's experiments on traction on roads, as reported in "Redtenbacher's Resultate," viz: two-wheeled *carts*, having wheels 64 in. and 78 in. respectively, in diameter, and axles $2\frac{1}{2}$ in. diameter, with tyres 4 in. and 5 in. wide:

	For 64 in. wheels.	For 78 in. wheels.
On very good macadam	$\frac{1}{66.2}$	$\frac{1}{82.8}$
On good paved road........	$\frac{1}{86.3}$	$\frac{1}{107.9}$
Parisian paved roads	$\frac{1}{79.9}$	$\frac{1}{99.9}$

Telford's older experiments gave $\frac{1}{71}$ on paved roads, and $\frac{1}{51}$ on macadam; also, I believe, with common laden wagons without springs.

Now for the other side of the question: Weisbach, in his "Ingenieur and Maschinen Mechanik," latest edition, 1865, second volume, page 323, computes the work done in walking on a level road to be equal to the weight of the person multiplied by $\frac{1}{12}$th of the speed per minute.

Now, if we suppose a man to weigh 140 lbs., and to walk at the rate of 3 miles per hour, we should have, by Weisbach's rule, $140 \times \frac{264}{12} = 3080$ foot-pounds per minute as the work done by walking.

I compute the traction for a bicycle to be at the very *outside* $\frac{1}{70}$th when going about 10 miles per hour; for, as a carriage, the velocipede is nearly perfection, and is fitted with a spring, Taking the weight of man and machine together as 210 lbs., and traction at $\frac{1}{70}$th, we should get for the speed of velocipede, when the rider worked up to the same power as when on foot, $\frac{3080}{3} = 1026.66$ ft. per minute, or about 11.6 miles per hour.

I think Weisbach's estimate of walking to be too high, and my own of the traction for a bicycle to be too high also. If we thus estimate walking to be equal to 1820 foot-pounds, and traction at $\frac{1}{100}$th, we get a speed of 10.3 miles per hour for the velocipede. It must, however, be remembered that it takes *months* of practice to *fully* acquire the use of a "two-wheeled horse."

COAL PRODUCT OF GREAT BRITAIN.—The production of coal in Great Britain was, in 1867, according to the returns given in the "Mineral Statistics," 104,500,480 tons. In 1868, according to the returns of the Inspectors of Coal Mines, the quantity was 104,566,959 tons. Of this the exports, according to the returns of the Board of Trade, were as follows:

Name of Country.	Quantity.	Declared Value.
	Tons.	£
Russia	623,767	306,103
Sweden	336,099	162,971
Denmark..................	835,669	367,721

A CEMENT FOR LEATHER is made by mixing ten parts of sulphide of carbon with one of oil of turpentine, and then adding enough gutta-percha to make a tough thickly flowing liquid. One essential pre-requisite to a thorough union of the parts consists in freedom of the surfaces to be joined from grease. This may be accomplished by laying a cloth upon them and applying a hot iron for a time. The cement is then applied to both pieces, the surfaces brought in contact, and pressure applied until the joint is dry.

Improved Machine Tools.—Mr. John Woolfield, of the Liverpool Works, Soho, who has recently commenced the manufacture of all kinds of machine tools, is introducing some improvements of his own design in connection with lathes. All lathes, up to fifteen inch centers, he fits with hardened steel, conical spindles and bearings. The slide-rest saddle and center-head he fits with steel screws and nut-boxes. In planing machines the advantage of this arrangement is especially obvious, yet it is frequently ignored by makers of first-class repute.—The saddle-slides are so constructed as to protect the screw that moves them from injury or dirt. The surfacing motion is new, good and inexpensive. A referencé to the processes of lathe making will afford some idea of the extreme care required to produce an excellent article. The first process is the boring of the head. Simultaneously, with this operation, the smith forges the spindles and bushes. This is a very difficult matter. First-rate smiths are not always able to produce a sound lathe spindle. The iron is first forged into the required shape, and a piece of double shear steel is welded round it to form the neck or bearing. Should this not be perfectly sound, it is pretty sure to "fly" in hardening. The bushes are steel cylinders, forged of double shear steel, and lapped with the best iron. The welding here is required to be done perfectly.—When these steel bushes are annealed they go to the turner, and turned parallel outside. Then they are subjected to a red heat, and suddenly immersed in running water; and should the slightest flaw occur in the weld, they crack and have to be thrown aside as wasters. If all goes well they are driven into the headstock bored to receive them, and are lapped true and clear, or, in other words, polished by means of a lead lap running at a remarkable speed. The spindle is annealed, then turned, heated to nearly a white heat, and plunged into a stream of water icy-cold. This is a severe trial of the smith's work. The next process is that of polishing. This is effected by placing it in a lathe and causing it to revolve slowly, an emery wheel running at considerable velocity in a contrary direction, until it is highly polished. Thus the spindle is a perfect "fit" when put into the bearings. The slide-rest and saddle are planed perfectly true, and then scraped and smoothed until the various parts, when put tightly together, will slide freely upon each other, a process requiring great care, skill and attention. Caution is especially required in planing slide-rests, beds, &c., lest they should spring when being fastened upon the planing machine. Long lathe beds require especial care. The saddle and bed both require to be scraped true, until they slide freely along the bed from end to end. Great care and nicety of finish is requisite for the leading screw.—In the construction of drilling machines, steel spindles are now superseding those of iron, the latter being liable to bend when subjected to a sudden jerk. Mr. Woolfield has recently patented a corrugating machine, which is estimated to perform ten times the work of the ordinary press, without subjecting the metal to undue strains. There can be no doubt about the glaring imperfections of the ordinary process, both in regard to economy and excellence of workmanship —*Cor. Engineer.*

We would recommend the correspondent of the "Engineer" to visit the Philadelphia tool-building shops. Much of this practice is old, and the use of iron spindles is all out of date.—*Ed. V. N. M.*

Gasholders.—Of the large number of gasholders in and near London, the greater proportion were made in the neighborhood of Birmingham. The largest gasholder in existence, that of 230 ft. diameter and 3,000,000 cubic feet capacity, at the Fulham station of the Imperial Gaslight Company, was made by Messrs. Westwood & Wright, of Dudley, the cast-iron work having been turned out by the Stavely Company.

Of the makers still nearer Birmingham, Messrs. Thomas Piggott & Sons, and Messrs. Hortons' gasholders are well known to probably nearly all the gas engineers in the kingdom. The last named firm have lately secured the contract for a large holder at the Western Gasworks, London, while Messrs. Piggotts are engaged upon one of 150 ft. diameter for Preston. Their largest holder was one, we believe, put up in Belfast, and 180 ft. in diameter.

The hydraulic punching and riveting machinery at Messrs. Piggotts' is extremely effective. In the rectangular plates any number of holes up to, we believe, 154, are punched at a single blow, and to the exact pitch. Originally the piston within a vertical steam cylinder of about 4 ft. diameter, and worked with 50 lbs. steam, had a rod or hydraulic plunger of 4 or 5 in. diameter, which was driven home with a force of perhaps 40 tons, equal to at least 2 tons per inch, forcing water equal to its own solid contents into an accumulator, from which it was let on, as required, to a pair of vertical 9 in. rams, placed over the bed of the punching machine. These drove down the punching head, carrying the punches, which were turned with shanks of a diameter equal to the intended pitch, and secured in rows, and with their shanks in contact, in grooves properly formed around the punching head. Each alternate punch was made ⅜ths inch longer than its neighbor on either side, so that although a single blow sent all the punches through the plate with a single report like that of a pistol, but one-half of the punches actually went through at once. The work thus done was exact, indeed perfection. Instead of the large steam cylinder, a pair of rotative pumping engines are now employed, the working pressure being 35 cwt. to 2 tons per square inch.

The hydraulic riveting is performed also by hydraulic pressure, at an average rate of thirty rivets per minute, the rate often rising, for a short time, to one per second.

Nothing would more nearly perfect the working of gasholder plates than the contrivance of a machine, if that be possible, for taking out the "buckles." This operation has now to be performed by hand, and it requires no small skill to effect it properly.—*Engineering.*

Cast-iron Tubes for water or gas are now made in England by turning off one end conically, and boring out the ends of the tubes to which it is to be fitted at the same angle, so that the end of one tube may be inserted into the other without the addition of the ordinary cement. The junction is effected very quickly, and the joint is perfectly tight. Pipes thirty-six inches in diameter have been perfectly joined in this way. Liverpool has about ninety miles of gas-pipe with this joint, and the leakage is said to be much less than in other cities.

Flexible Pipes are much used in Paris for rounding slight curves.

VAN NOSTRAND'S
ECLECTIC
ENGINEERING MAGAZINE.

No. XII.—DECEMBER, 1869.—Vol. I.

THE LATE ORDNANCE COMMITTEE.

Written for Van Nostrand's Magazine.

By the two reports of the Select Committee on Ordnance, submitted to Congress July 17th, 1868 and Feb. 15th, 1869, the Ordnance Departments of the Army and Navy have been subjected to great reproach. In addition to charges seriously compromising the official integrity of certain officers, the whole service has been sweepingly condemned as incompetent and unqualified, persistently adherent to false practice and theory, and impervious to improvement. Its abolition is recommended, with the substitution of a board composed of officers and civilians. Knowing the causes which led to these investigations and reports, and having some knowledge of the persons who procured the appointment of the committee, and of their motives and antecedents, we have deemed it proper to lay before the public, so far as we may, a review of the whole matter. It need hardly be said that the subject is an important one, relating as it does to a most essential branch of the executive department of government, and the one charged with providing materials of national defense.

The report of July 17th, 1868, received considerable notice through various newspapers, and is already known to the public. It related, almost exclusively, to the action of the Chief of Ordnance in the purchase of rifle projectiles. The other report has received less public notice, although it was more sweeping in character and significant in language, being nothing less than a general arraignment and condemnation of the Ordnance Department in the strongest terms. We have deemed it proper to discuss the two reports separately, and analyze them in detail.

Fortunately, we are able to decline entering into any examination looking to the refutation of the charges contained in the first report, since this has been done most satisfactorily by the court of inquiry, summoned at the request of the officer whose record had been assailed. The charges made by the committee are not only met, in the finding of the court, by a flat denial, but are virtually pronounced to be utterly without foundation in facts, and the accused is directly complimented for his integrity and efficiency. The characters of the officers constituting the court will certainly place its finding beyond cavil on the ground of partiality or bias, or any ulterior motive, while the exhaustive investigation, extending over six months of almost uninterrupted session, and conducted by able and expert counsel on both sides, to whom was allotted the largest liberty in respect to the range of testimony, will be a good guarantee of completeness and accuracy.

In comparing the findings of the court and of the committee, we first note the fact that the evidence, upon which the charges rested, was substantially the same before both. The same witnesses were summoned for the prosecution before the court as appeared in the committee room, and reiterated their statements; the documentary evidence in the two examinations differed only in being much more complete at the second than at the first. It may then be fairly asked, how happens it that the two bodies arrived at diametrically opposite conclusions? If there had been evidence enough before the committee to procure such a strong condemnation as was actually delivered, the same evidence before the court ought to have, at least, qualified the acquittal. It will be borne in mind that the diversity of opinion was upon matters of simple fact and not of law. Had it been the former, it might readily be passed over as an ordinary difference of opinion upon a matter of principle, illustrating two ways of viewing the same thing, and both defensible; but in truth each body was called upon to report facts, and these are matters such as the law holds every hod-carrier and tinker capable of deciding. So cogent is this consideration that we are driven to the conclusion that, in one body or the other, the decision was determined, not by candid, impartial judgment upon fair evidence, but by a predetermination to convict or acquit without regard to the evidence. Unhappily a perusal of the two records allows no other interpretation. The issue was a simple one. Had the Chief of Ordnance been guilty of fraudulent transactions, and if so, what were they? No mere error of judgment, or difference of opinion, as between impartial men, could, under the circumstances, account for such contradictory decisions. On which side does the defect of justice lie?

A comparison of the constitution and functions of the two bodies may indicate where we may presumptively look for an explanation. The court was composed of three members and a Judge Advocate, viz: Gens. Thomas, Hancock, and Terry, and Judge Advocate Gen. Holt. The members of the court were sworn* to well and truly examine and inquire, according to the evidence, into the matter before them. The examination was by sworn testimony, in the presence of the accused, and was conducted by counsel on both sides. The rules of evidence were the same as in all other military courts, which conform to the practice of United States civil courts, as nearly as their peculiar constitution will permit.

The select committee was very differently constituted. It consisted of Messrs. Howard, Cameron, and Drake, of the Senate, and Messrs. Butler, Logan, and Schenck, of the House. Messrs. Butler and Logan were appointed a sub-committee to conduct the examination, the other members taking only a nominal part in it, and being seldom present in the committee room. Mr. Butler was almost the sole examiner. He was governed by no rules of evidence, and no precedents in the matter of practice, except the swearing of witnesses. No counsel was admitted, and no accused person being formally recognized, the really accused party was not present. It will be readily seen that a person so charged with the grave responsibility of furnishing Congress with information, which may be made the basis of intelligent legislation, and vested by that body with plenary power to subpœna witnesses from every corner of the land, without restriction as to whom he shall or shall not summon, or what testimony shall be admitted, and what refused, requires to be a person of surpassing ability, and most especially, to be above all prejudices. He is not merely an examiner, but a judge, whose decision is the only authoritative guide of Congress. We are averse to any invidious comparisons between persons of high distinction, but at the risk of making one, we are compelled to notice the complaints of Gen. Dyer's prosecutors that the finding of the court was "corrupt, arbitrary and illegal," arising out of the prejudices of the members, and a determination on their part to shield a brother officer, regardless of his crimes or the demands of justice. It happens that Gen. Butler has never been at any pains to conceal his sentiments towards the regular army, and doubtless many can recall his remarks at the last session when the army bill was before the House. We would like to propound the question, in view of these utterances, whether Gen. Dyer was not as liable to encounter adverse prejudices before the committee, as his prosecutors were before the court. We are quite content to leave it to the public to judge, whether the truth, in this particular case, was any more likely to suffer from the prejudices of Gens. Thomas, Hancock and Terry, than from those of Mr. Butler. Be that as it may, no one will venture to deny that the strictest impartiality was essential to the position Mr. Butler occupied. And yet, we do not hesitate to say, that he at once assumed the *rôle* of a prosecuting attorney, and conducted his examination in a thoroughly *ex parte* manner, while no opportunity was conceded to develop the other side by other testimony, and by cross-examination. Those who are familiar with legal processes may readily form some idea of what an astute lawyer like Mr. Butler

---

* Article of War 93.

might be able to accomplish under such circumstances. But this was by no means the worst feature of the case: for after examining witnesses without interference, he was to bring in the verdict. To the most impartial man such a position would involve the gravest responsibility. How did Mr. Butler meet its obligations?

In a technical examination before a legislative committee, where the members are not thoroughly versed, or "expert," in the subject matter of inquiry, it is customary to employ the advice and assistance of expert examiners. Mr. Butler had occasion to avail himself of such assistance, selecting for the purpose Mr. Clifford Arrick of St. Clairsville, Ohio. Most certainly the selection was an astounding one. The important part taken by Mr. Arrick, in the course of the imbroglio, renders necessary such a sketch of him as we are able to give. Some time prior to the war he was an attorney, and subsequently, an examiner in the Patent Office. Here, having become familiar with the progress of invention in rifle projectiles, he at length became interested in an invention known as the Eureka projectile, patented by a Mr. Stafford of New York. By a piece of sharp practice Mr. Arrick obtained a patent for the same projectile in his own name*, and proceeded to urge its merits upon the Ordnance Bureau. Now, shorn of all verbiage, and reduced to its lowest terms, the report of July 17th, 1868, arraigns, tries, convicts and sentences Gen. Dyer, *because he declined to establish the Eureka projectile as the standard service rifle projectile, to the exclusion of all others as worthless*, the ascribed motive being pecuniary interest in a projectile of his own invention. We must digress a little. In the year 1857, Capt. Dyer invented a projectile, which may be considered as the type of a large and varied class. Subsequent developments have shown that he was not the first to apply, what may be termed the essential feature of that class, viz: an expansible cup of soft metal attached to the base of it. Still, he was *an* inventor, having at the time no knowledge of similar devices, and was the first to apply it, in this country, with any degree of success. The opening of the war and the success of rifled cannon abroad gave rise to numberless inventions, and modifications of inventions, of similar purpose, so that the year 1863 witnessed the establishment of several standard varieties, which were used with what were then considered very fair results. Though exhibiting wide differences in mechanical details, they all possessed one common feature, viz: a soft, expansible portion: compressible into the grooves of the gun by the force of discharge. This feature is a radical one in American ordnance, at present, and is sharply distinguished from the system more commonly adopted in Europe, which is exemplified by a projectile having grooves and lands fitting the bore of the gun. Confining ourselves to the American system, its extremes might be well represented by the Parrot and Hotchkiss. The numerous species, which may be said to lie between these extremes, were mostly developed as early as 1863 — all subsequent variations being hardly more than varieties. Some of them underwent modifications, mainly with a view to correct imperfections made apparent by actual service. On the whole, however, no new principle was brought to light. The Dyer projectile meantime had been superseded by the Parrot—its inventor, and, in truth, every other ordnance officer, being so wholly engrossed by administrative duties that no time was found to remedy certain deficiencies disclosed by practice. Up to the time of Gen. Dyer's accession to the command of the Ordnance Department, Mr. John Absterdam had presented two modifications of it, which did not make it in any respect superior and probably not equal to other standard projectiles. Yet it appears to have been the general conviction of the most expert ordnance officers, that a projectile with a soft metal cup at the base *ought* to be the best projectile* and, if properly constructed, would certainly answer the purpose more perfectly than any other. Its defects were felt to be matters of detail and not of principle. These opinions were amply justified by later experiments, when the Dyer projectiles had been subjected to important modifications.

In the latter part of 1863, Mr. Clifford Arrick first exhibited the Eureka projectile

*Singularly enough, Mr. Arrick had been employed as counsel by Stafford in an interference case, in which he succeeded in proving to the satisfaction of the commissioner, that, among several claimants, Stafford was the first inventor. Stafford subsequently assigned his patent to a company of which Mr. Arrick was the agent. Soon after, Mr. Arrick files an application for a patent for this identical invention in his own name, an interference is declared, and, by collusion, Stafford's assignees *fail to appear*! The patent therefore goes to Mr. Arrick by default. (Court of Inquiry Vol II. pp., 223).

* For field service at least.

to the ordnance bureau, and obtained an order for a preliminary trial, at which the action of the smaller calibers was pronounced "fair."* No action was taken by the bureau upon the report, and in the following May, a few more were tried at Washington Arsenal. The experimenting officer reported favorably upon them, with the exception, that the fuses failed to ignite, owing to the entire closure of the windage. After Gen. Dyer acceded to the command of the department, in September, 1864, an order was given for a further trial with 20-pounders having improved means for igniting the fuses. This trial elicited a highly commendatory report,† which warranted their trial on a more extended scale, in competition with standard projectiles;—the caliber selected being the 4.2 inch or 30-pounder. It is held to be a tolerably safe rule, among experts, that a projectile succeeding well in a larger gun will probably succeed well in a smaller, but not *vice-versa*—so that this trial was expected to furnish data only for 30-pounders and smaller projectiles. It was one of considerable importance, for it was expected to result in the restriction of the number of standard varieties. The competing patterns were the Hotchkiss ‡, Parrott, Schenkl, Eureka and Absterdam. Early in the trial the Absterdam, made in conformity with his second patent, and closely resembling the older Dyer projectile, failed most signally. But Mr. Absterdam had just obtained§ a third patent, and during the progress of the trial substituted the projectiles made in conformity with it for those which were giving such disastrous results. The trial terminated less decisively than was hoped, and failed to furnish means|| for a rigid comparison. The Eureka had shown itself to be a good projectile, but not uniformly so. On the other hand, the record of the new Absterdam was decidedly better, while the Hotchkiss, at the very last of the trial, gave, so far as tried, the best results of all;* in brief, the whole question was still in abeyance, except as regarded the Parrott† and Schenkl, which were less satisfactory than either of the others. At all events there was nothing whatever in the trial to warrant the enormous claim put forth by Mr. Arrick, that the Eureka had proved itself to be so decidedly superior to all others, that the Chief of Ordnance was bound to make it the standard service projectile, to the exclusion of all others as worthless.‡ That the court took that view of the case and scouted such a preposterous idea is clear, when it characterized the action of Gen. Dyer as merely an exercise of that discretion which unquestionably belongs to his position. Yet this was precisely Mr. Arrick's claim, as nearly as words can express it. He urged it in a large number of letters§ of portentous

* Made at West Point by Captain D. W. Flagler.

† The Washington trials were made by Lieutenant William Prince, and his reports, forwarded by Major Benton with a formal endorsement, were attributed by the committee to the latter officer.

‡ There were two Hotchkiss projectiles at this trial. The one first employed was the old one, so familiar to all our artillery officers; this is figured in the plate. The other one was quite new, differing from the old one *toto cœlo*. It was provided with an expanding cup at the base. It was not presented for trial until too late to obtain thorough results. By an oversight it was omitted from the plate.

§ The drawings in the plate are the second and third Absterdam patents; the one with the brass sabot being the third.

|| The following is an abstract of the results of the trial as tabulated:

Between February 11th and May 17th, the firings gave the following results: Parrott, 344 shots fired, with 55 bad shots; Hotchkiss (old pattern), 346 shots fired, with 31 bad shots; Absterdam, 232 shots fired, with 19 bad shots; Eureka, 200 shots fired, with 27 bad shots; Hotchkiss (new pattern), 52 shots fired and no bad shots. Ratio of bad shots: Parrott, .16; Hotchkiss (old), .089; Absterdam, .082; Eureka, .135; Hotchkiss (new), none. The Eureka had a very slight advantage over the others in initial velocity and range, in the general average, but was not uniform. The above *comparative* results were dated February 28th, 1865. The results with the new Hotchkiss were not received until June.

TABLE

Of comparative firings of 40 *shots of each variety at* 1,260 *yards, in February*, 1865.

	Total No. of shots.	No. of bad shots.	Percentage of bad shots.	Initial velocity; feet per second.	Direct hits out of 20 shots for range.	Ricochet hits.	Misses.	Vertical deviation, feet.	Horizontal deviation, feet.	Mean deviation, feet.
Parrott ...	40	10	.25	1,201	9	3	8	3.93	9.68	10.4
Hotchkiss..	40	5	.155	1,221	8	3	9	4.60	6.60	8.07
Absterdam	40	3	.075	1,221	6	8	6	2.33	6.23	6.65
Eureka ...	40	10	.25	1,247	10	5	5	3.90	6.70	7.75
Schenkl ..	40	37	.925	1,196						

* Only 55 rounds were fired. The results were known only after the war closed.

† To show upon what slight structural differences the efficiency of a projectile may depend, it may be stated, that the only essential difference between the Parrott and the Absterdam is, that in the former the sabot, or base ring, is "flush" with the base of the shot, while in the latter it extends about .8 of an inch beyond it, forming a cup.

‡ Mr. Arrick made this claim very explicitly and repeatedly. See letters of Arrick to Dyer, dated Jan. 31st, Feb. 6th and 9th, 1866. Court of Inq., Vol. I, pp. 181–183; also id., pp. 196–206.

§ In the month of Oct., 1866, alone, he addressed nine long letters to the bureau on the subject.

length, in which he lost sight of all reason and decorum. He spoke of the demands of the public service upon the Chief of Ordnance, which he was not at liberty to disregard, and insinuated that he was rejecting the only device worth having, by reason of his personal interest in a worthless contrivance which he was endeavoring to thrust upon the service under cover of a false name*, and through the agency of a man of straw. Of course such letters were eminently calculated to carry conviction with them, and to create a warm interest in the Eureka. After a large number of them had accummulated, Gen. Dyer requested Mr. Arrick to state specifically and exactly what he wanted, and received in reply a twenty paged letter,† amplifying the merits of the projectile, and culminating in seven propositions asserting its superiority over every other known device. He then desired the Chief of Ordnance to assent to, or deny them, or in case of doubt to appoint a commission to determine the question upon the records as they then stood. To this Gen. Dyer replied,‡ declining to be catechized; that the *comparative* merits of the Eureka projectile were understood by him, and that he had on hand over 5,000 of them, which would enable him to test their full merits whenever it was expedient to do so. In short, he refused to accept the alternatives of either rejecting altogether a good projectile, or of over-stating and overvaluing its merits.

No person of ordinary intelligence will have any difficulty in correctly appreciating the merits of this controversy. Mr. Arrick claimed to have an invention which ought to supersede every other for similar objects. But was there ever a patentee who was not ready and eager to claim the same thing? For five years or more the Ordnance Office was daily thronged with sanguine inventors, and owners of inventions, making the same claim, each strenuously asserting that he had anticipated for many years to come all possible improvement in a particular direction, and thinking that the Chief of Ordnance, and all his subordinates, were the embodiments of stupidity, because they thought differently. Each inventor seemed to entertain the idea that the Government was bound to accept off hand, or, at least, to try his own particular contrivance. Let some statistician calculate the expense of satisfying, either by acceptance or trial, the expectations of these gentlemen, and he will be edified. Are men of business in the habit of purchasing new inventions without knowing their merits? Are they in the habit of testing them for the sole emolument of the inventors? In a word, is not the usual and proper course, in such matters, to purchase them if you think they will pay, and to let them alone if you don't? Now, what earthly reason is there why the Government, through its officials, should throw away this prudent and universal practice? These officers are required to judge of the exigencies of their respective departments, precisely as the proprietors of private establishments judge of theirs, and to manage them in the interest of the Government, and not of inventors and contractors. Mr. Arrick demanded, in no very gentle terms, that his projectile be accepted, against the judgment of the department, and upon no decisive record, though he afterwards proposed to subject it to the form of a trial§ which would cost $20,000. As the department had on hand an enormous supply of projectiles, which, in its opinion, were as good as, not to say better than, the Eureka was likely to prove, it was deemed inexpedient to spend a large amount of public money in settling a question of no practical importance at that juncture. Even admitting, for the sake of argument, that the Eureka may prove to be somewhat superior to any other ever urged upon the bureau, is the Government, at the close of a gigantic war, and weighed down with debt, to incur further expense in demonstrating the value of an article it does not want?

After four years of solicitation; after he had become intolerable to the bureau and everybody connected with it, Mr. Arrick came to the safe conclusion that he had spent much time and money to no purpose. We believe his friends will not assert that, in his wonderful persistence, he was so disinterested as to work from purely patriotic

* Letters of Arrick to Dyer, Feb. 9th, 1866, Court of Inq. I, 182, and id., Oct. 16th, p. 198. Mr. Arrick claimed that the Absterdam was but another name for the Dyer projectile, and that Gen. Dyer was receiving royalty on the purchases, and using Absterdam to conceal the transaction. This is the gist of some of the accusations in the report of the committee.

† Letter of Arrick, Oct. 25th, 1866, Court of Inq., Vol. I, p. 201.

§ Arrick to Dyer, July 9th, 1867. Id., p. 222.

motives, nor are we aware that he claims any motive but the pursuit of emolument; and when we find him thoroughly committed to the serious undertaking of the overthrow of the Ordnance Department, we see no escape from the conclusion that his incentives were money, and, perhaps, revenge. We are by no means left to conjecture alone on this point. He expressed himself ready to relent if his claims were conceded by the bureau*, but in the other event he was resolved to spare no effort to demolish it. It seems that he did not lack powerful co-operation. We are not aware by what means his determination was made known to the Select Committee, nor is it material. His own account of the affair is, that he knew the committee wanted him, and were about to send for him, and he anticipated their summons†. And so Mr. Arrick became the expert examiner and adviser of the committee in the investigation of Gen. Dyer's action in the purchase of rifle projectiles.

Were it necessary we would detail some of the operations by which testimony before the committee was perverted; how Mr. Absterdam was made to testify that he had no patents, when he had them in his pocket; how indignant the old gentleman got when he told the court that his evidence, as it appeared in the record of the committee, was a mutilation, a forgery, and he repudiated it‡; how the Absterdam projectile, of the third patent, which had been purchased so extensively, was shown to be "absolutely worthless" by quoting the record of projectiles made under the second patent§—a different affair altogether; how a poor woman was made to testify‖ that Gen. Dyer had claimed a royalty on these projectiles in the Ordnance office, and in the presence of several individuals; a statement which Mr. Field, by a few minutes cross-examination, showed to be an ambiguous perversion of a remark which did that officer no little honor. But we pass them by, for they are all rendered ineffectual by the finding of the court.

A fitting termination to this marvelous investigation was the preparation of the report. After giving over the body of the Chief of Ordnance to his adversaries, to wreak such vengeance upon it as they saw fit, and to toss and gore it in the committee-room, it might be thought proper that the drawing and quartering of the remains should have been done by the representatives of the law. But the committee thought otherwise.

Mr. Arrick states. in his testimony before the court, that, by a general understanding with the committee, he wrote the report, presented it to Mr. Butler, who read it over, reduced it by striking out certain passages, and re-committed it to Arrick, who made the corrections and again submitted it to Mr. Butler, by whom it was accepted and presented to the full committee, who in turn delivered it to Congress as the report, in part, of the Select Committee on Ordnance. *The whole text was written by Mr. Arrick, verbatim, as it now appears, with the exception of the last three lines.** As nearly as we can figure it, this report cost the country in the neighborhood of $200,000, and the net result of the expenditure is, that Congress and the country have been enlightened as to Mr. Arrick's opinion of the Chief of Ordnance! Why! Mr. Arrick was boiling over to give it to them for nothing but the asking!

The next subject, covered by the report of Feb. 15th, 1869, was that of heavy guns. Mr. Butler being occupied with the impeachment case, took no active part in this—his place being, in a measure, supplied by Mr. Howard. This subject being far more difficult in point of scientific principles involved, the same necessity existed for a resort to expert assistance. That an eminently qualified person should be selected was a matter of the first importance. To convey to Congress information which would enable that body to form a correct, comprehensive, and concise opinion of the state of modern ordnance in general, and of American ordnance in particular, is a task from which the most accomplished expert in the land might well shrink.

In England, during the last fifteen years, not less than £25,000,000 sterling have been expended by Government upon experimental artillery. Enormous sums, of which we have no record before us, have been expended in a similar way by the continental nations of Europe. The most accomplished engineers, army and navy officers, iron masters and mechanics, have added their severest

labors, and most strenuous efforts of intellect and capital, to aid in the solution of the ordnance problem. In England, France and Germany, where new processes and new machinery for the manipulation of iron and steel have succeeded each other with marvelous rapidity, and upon a constantly increasing scale of power, the utmost that has been looked forward to, is some process which will render practicable and reliable the construction of the enormous guns demanded by modern warfare. In America, owing to the greater scarcity and cost of capital, and the backward condition of machinery for manipulating large masses of metal, no such immense establishments as those of Sheffield, Birmingham and Essen, are in existence. The attention of ordnance officers and civilians has therefore been confined to such materials as the workshops of the country are capable of manipulating, and that material, so far as the largest guns are concerned, is cast-iron. In this limited field have been employed the talents and energy of our most practical and learned constructors. The question of ordnance has long involved the labor of the highest mechanical genius, the most ponderous machinery, the largest accumulations of private capital, and the most lavish expenditure of public funds of any scientific question before the civilized world. Whom, then, did the honorable chairman of the Select Committee on Ordnance select, as his representative, to elucidate and expound this lofty subject to the national legislature? We have no hesitation in asserting that, out of the thirty-five millions of people in these States, Mr. Howard selected the man possessing the most obnoxious disqualifications, and the greatest number of them.

We pause here to apologize to the readers of the ECLECTIC. We are adequately impressed with a sense of the dignity and impersonality which should characterize all professional discussions. We also asseverate a profound respect for the wisdom, patriotism, and official dignity of our national legislature, which we desire to extend to all its constituent parts and members. But we find ourselves embarked in a serious discussion, which brings us face to face with a most anomalous state of affairs. On the one hand, we find a man making the loftiest kind of pretensions to professional science, and yet is at the farthest remove from it. These pretensions are not made quietly, modestly, and deferentially, in the ordinary range of private or literary discussion, but coarsely, blatantly, and abusively, before a high inquest of national importance. On the other hand, we find a congressional committee accepting implicitly these false pretensions, and using their high powers to push their consequences to the uttermost. We have a general interest in this matter, as a lover of truth and a citizen of the republic, and we have a special interest in it as a member of that small but select body, whose professional reputation is immediately assailed. What is our duty in the premises? Is there any alternative but to tell the whole truth, regardless alike of personalities, or of the character of any committee whom our honorable Congress may see fit to designate?

The person we refer to is Mr. Norman Wiard. He, too, was a disappointed aspirant for wealth through dealings with the Ordnance Department. Like Mr. Arrick, he had an invention to offer, the adoption of which he had urged through long and weary years, with an energy and importunity such as is known only to that desperate class who throng the departments and infest the portals of the capitol. Many of them are men of capacity, and certainly some of them mean to be honest. Some, too, have personal qualities, which, if exercised in a moderate but honest capacity, and controlled by moderate and rational ambition, would make them invaluable members of the community. But they are men of desperate need, and, at the same time, bitten by an inordinate desire to accumulate wealth out of public patronage. Their ravening hunger obliterates all perception of public interest and morality. Now, if eight years of untiring solicitation for the Government acceptance of chimerical schemes, the receipt of $136,809 in Treasury drafts and certificates, for which the Government cannot, and never could, show $25,000 worth* of effects; the repeated memoralizing of Congress† against zealous and upright officers, and in favor of a corrupt scheme of private emolument at the public expense—if hob-a-nobbing with

* All of the ordnance material furnished by Mr. Wiard to the army and navy, excepting such as was made in conformity with regulation patterns, was found to be unserviceable in the field. The army commanders who had requested a supply of his semi-steel guns, were the first to request their withdrawal.

† There are several memorials of Mr. Wiard to Congress, the most infamous being that which was referred to the Committee on the Conduct of the War, in 1865.

those Congressmen who are not particular about the company they keep, and persuading them to recommend that Congress appropriate $125,000 for a claim* which is fraudulent in its very essence—if instigating and procuring the appointment of a congressional committee† to recommend the dismissal of a select corps of zealous public servants, for no other earthly reason than because they refused to lend themselves to these iniquitous schemes; if these things entitle a man to a high position in the category of the "third house," as we have described it, then Mr. Norman Wiard belongs there. We wish it distinctly understood that we make no charges which we cannot prove under the seal of official record, and we shall in due time give the proper references.

We shall first proceed to characterize the peculiar invention he has sought to establish. Mr. Wiard was occupied, in the year 1862, in the fabrication of some semi-steel 50-pounders for the Navy Department. When subjected to a very moderate test, these guns burst with surprising facility. In speculating upon the reason why a metal, having such high tensile strength, should exhibit an endurance inferior to cast-iron, he came to the conclusion (by what logical process he does not inform us) that some agency was concerned in the destructive effects of firing, other than the mere expansive force of powder. It at length appeared to him that the intense heat of the ignited powder, together with that produced by the friction of the shot against the surface of the bore, would occasion a difference of temperature, as between the interior and exterior, tending to compress the former and extend the latter. Guns fired rapidly, would, in this way, be subjected to a constantly increasing tension, which, added to the force of the discharge, would ultimately produce rupture. Satisfied that he had solved the problem, and that his solution covered every case of rupture, he applied himself to the devising of a gun which would compensate this difficulty. In 1864, after much solicitation, he procured from the Navy Department a contract for the construction of two 15-in. guns upon his plan, designed to obviate the supposed effects of heat. The first gun was condemned in the pit; the second was finished and broke into many pieces at the first discharge. The department did not deem it advisable to expend any more money upon an experiment of this character, and although Mr. Wiard's importunities have been very great, they have been invariably declined.

A discussion of the hypothesis he has advanced, we must decline entering into, further than to state a few facts. That a gun is heated by firing, that the heat so produced is greater in the interior of the gun than at the exterior, and that the difference of temperature may, in most cases, produce to a small extent the tensions Mr. Wiard assumes, are doubtless true. But the question is one of degree. Mr. Wiard assumes that these tensions are something enormous—every gun founder and constructor of experience knows them to be so small as to be practically immaterial. But whether they be great or little, his proposed plan for obviating them will appeal only to "the risibles" of the true mechanic, and if it has never been duly characterized by competent authority, it is because such authority has deemed it too bizarre and whimsical to dignify it with notice. There are two ways of substantiating a physical hypothesis—one analytically, by mathematical demonstration; the other empirically, by experiment, and a complete demonstration should properly involve both. Mr. Wiard has given no analysis of the effect of heat upon the metal of a gun, and his hypothesis, therefore, rests upon no theoretical basis. We cannot recognize the statements he has made concerning the effects of heat, or sudden cooling, upon various masses of metal as having any bearing whatever upon the thing to be proved. When he submits an analysis showing, within a reasonable approximation, the amount of heat communicated to the gun, the rate at which it is conducted through the mass, the degrees of tension produced, and the relations of these forces to the ultimate strength and elasticity of the iron, intelligent mechanics will be happy to give it such careful and respectful consideration as it merits. At present they have no tangible theory to work upon, but only a few incoherent assertions on his own authority, which is opposed to that of all constructors known to the public. As for facts, they are all against the hypothesis. No gun ever burst under circumstances which could prop-

* Fortieth Congress, Third Session, House Report No. 6.

† There is no room for doubt at whose instigation the committee was appointed. The numerous letters of Arrick, Wiard, and Horatio Ames (see Vol. II, Court of Inq.), contain abundant evidence that they procured it, and were able to control it.

erly warrant the assumption that it was due to any cause, other than the expansive force of gunpowder. But numerous experiments* have been made with a view to test this question. Guns burst indifferently, whether fired rapidly or slowly, or, as in the case of some of Mr. Wiard's, at the first discharge, in which the assertion of such a cause is a contradiction of terms.

Mr. Arrick is a true expert, and the contrivance he urged upon the bureau had great merits; but Mr. Wiard is a charlatan, and his gun a mere monstrosity. In his evidence before the committee he undertakes to expound the nature of the mechanical forces involved in the action of gunpowder. Whoever will take the pains to read that exposition will, if he be versed in the doctrines of mechanical science, at once recognize the fact that the whole testimony is an imposture—a pretense—an aping of knowledge, which he does not possess, and never can possess, until he has at least gone through a course of study and instruction, such as is required of every school-boy who becomes a candidate for a bachelor's or professional degree. It is a bold attempt to persuade the committee that the laws of force, as taught by every mathematician since the days of Galileo, are foolish misconceptions, and that the only true wisdom the world has ever seen, has found its incarnation in Mr. Norman Wiard. The notions of this man are no ordinary errors. They are such as can exist only in the absence of a capacity to understand the fundamental principles of mechanics, as taught in every school book, and elaborated in every treatise, from the theory of falling bodies to the *Mechanique Céleste* of Laplace. Either the whole world beside is utterly wrong, or else Mr. Wiard is—not only in special deductions, but in the simplest principles, which every unbreeched school-boy is bound to know. Really, matters have come to a strange pass, when the Ordnance Department is to be compelled to defend, not merely its system of ordnance, but the first principles of Weissbach, Bartlett, and Moseley, against the assaults of an imposter. We should like to see Mr. Wiard, or anybody else, take his assumptions about the "projectile force" of powder,* and apply them to the fundamental equation $Q = \int P\,ds$, and to see where he will come out.

Whoever likes to contrast the insolence of ignorance with the modesty of true knowledge may turn to the testimony of Gen. Rodman. Here is an officer whose reputation as a man of high scientific attainment is world wide, and whose practical experience in gun founding is as extensive as that of any living man. His statement of the merits of the system which bears his name is qualified by a full acknowledgment of the limits of its advantages, and an humble sense of the difficulties which beset the whole subject, arising partly from a want of experimental knowledge, and partly from the unsuitable nature of the materials we have to deal with. Mr. Wiard, a man innocent of learning, who never made a reliable gun in his life, lays claim to complete knowledge, where all other men are silent, solves by a dictum every moot question, and charges other men with ignorance, stupidity and dishonesty.

But we have more serious charges to bring against Mr. Wiard than mere ignorance. In

* After the action of Fort Fisher, several 100-pdr. Parrotts were fired over 1,000 rounds each, one of the objects of the trial being to determine whether rapid firing exerted any appreciable effect. (Of course it is possible to fire more rapidly experimentally than in action, where time is consumed in sighting.) Nothing was developed by the experiment. It has become usual to conduct a part of the extreme proof of guns with the same view. No appreciable effect has ever been observed to result from rapid, as distinguished from slow firing. Out of the enormous quantity of experimental firings which have been made, it is a sheer impossibility that any such cause could escape detection if it had any real existence.

* Mr. Wiard seems to entertain the idea that the velocity of the projectile is the result of *two* forces, viz: the static pressure of the ignited powder, and the *vis viva* with which the powder is projected against the projectile. After elaborating this view with considerable minuteness, he then proceeds as follows:

"Q. What is the difference between the projectile force and the pressure of the powder, and has one a fixed and continuous relation to the other?

"A. The projectile force of the powder is the force equal to that which would be developed or exhibited in stopping the projectile. The pressure is that force which gives it motion in the gun, and it can be seen that if such a force as that acting upon the projectile should act against the surface of the bore in the gun, no material could be found from which guns could be made, which would not either enlarge the bore, or burst as a gun, unless it were from material which, if formed into a plate, and fixed upon the side of a ship as armor, would resist the impact of a shot from a gun without any indentation whatever. When a wrought iron shot is fired from a gun at a plate, which it does not penetrate to any considerable depth, the shot is flattened by the impact. If the pressure of the powder were not less than the projectile force, the shot would be invariably flattened to the same extent in the gun, which, however, is not the case."

We leave the educated mechanic to groan in spirit over this.

his testimony* he refers to a report of the Chief of Ordnance, which speaks of certain "ignorant, or designing persons" who have "hindered the furnishing by the Department of 1,915 large guns." Mr. Wiard says, "I hope you will credit me with having prevented the perpetration of a gigantic swindle thereby." We are much obliged to him for the word. We shall probably agree as to its meaning and differ only as to who is the swindler.

In October, 1861, he received from the Navy Department an order to finish a number of 7½ in. guns†, the blocks being furnished him. Having no means of his own he sub-let the work to one, William A. Miller, of New York. When nearly completed, an inspection was held, and it was reported that $5,270.00 had been earned, which amount was paid to Norman Wiard. Mr. Miller never saw a dollar of this money and held the guns as a lien. Their delivery was demanded of Mr. Wiard by the Navy Department, but he failed to respond and ultimately the guns were forcibly removed by the Commandant of the Brooklyn Navy Yard.

In August, 1861, Mr. Wiard received an informal contract to furnish the Navy Department with a number of semi-steel 50-pounders.‡ They were to be deliverd in lots of five, and upon the notification of the acceptance of each lot after inspection, an order for a new lot was to issue. The first six guns submitted for inspection failed§ most signally. Three of them burst by firing less than eleven rounds with five pounds of powder, and a fourth—the trial gun—had been disabled after some 350 charges. One of these guns, after bursting, was found to contain a false bottom, which had been inserted to hide an error of dimensions. In the investigation which followed, Mr. Wiard asserted his ignorance of the fraud and charged it upon various manufacturers and artizans who had immediate charge of the work. One of these persons acknowledged the sole responsibility and in his defense made some very significant disclosures. His statements were sustained by the affidavits of four men*, who were in no wise implicated in the fraud, and whose testimony is unimpeachable. It seems that the practice of doctoring sick guns was a most extensive one at the establishment where Mr. Wiard's 50-pounders were made, and that he himself inaugurated the system. Flaws were hammered up, seams brazed and holes plugged with screws.† Guns which had been rejected were artfully tinkered‡ and restored to their vacant places—all by Mr. Wiard's own orders in almost every case specifically, and against the repeated protests of his manufacturers.

Of these 50-pounders the Department accepted only one—the first and trial gun, which was paid for. Mr. Wiard made ten, of which four were never brought to trial. Of the other six, two were fired ten times without injury and landed by Mr. Wiard at the Navy Yard. They were never received by the Government, and yet Mr. Wiard presented a bill for them,§ amounting to $9,671.30. As the Department declined to pay for them, he proposed that the subject be submitted to a commission, promising to abide fully by its decision. The commission was appointed conformably to his request, gave the matter a full hearing, and reported adversely to his claim. We shall soon see how he kept his promise.

In April, 1863, Mr. Wiard entered into a formal contract‖ with the Navy Department to cast a 15-in. trial gun upon his peculiar plan, designed to obviate the effects of heat. When ready for trial he was to receive one-half the full price, which was to be 25 cents per pound, the balance to be paid when the trial was completed. In case of failure he was to be allowed to make a second gun under the same conditions, which, if successful, was to be considered as the trial gun. As we have already stated, the first gun was

* Testimony of Norman Wiard before committee. Report of February 15, 1869.

† See letter of Sec. of Navy to Senate 41st Congress, 1st Session, Senate Ex. Doc. No. 11, March 31st, 1869. This document is a compilation of official correspondence between Norman Wiard and officers of the Navy Department submitted without comment. The statement we give we vouch for as being a correct epitome of the statements therein contained.

‡ The whole history of these 50-pounders will be found in the document just referred to.

§ One was fired 350 times when it showed an excessive enlargement of the vent; one burst at the ninth fire; one at the tenth; one stripped a land at the first fire and exhibited at the tenth fire a crack about four feet long.

† Id.

‡ Every iron maker knows well enough that of all forms of iron the most treacherous and worthless is semi-steel as it is called. It is in effect a wretched half kneaded and half cooked variety of wrought iron utterly unsuitable for any purpose known to the arts.

§ Id.

‖ Id. The contract in full is published in the document referred to.

an imperfect casting; the second burst at the first fire, and terminated the contract. Mr. Wiard was paid $5,160.00 for the first gun,* and $4,295.00 for the second. In acknowledging the receipt he signed an explicit statement† that the acceptance was a final settlement of all claims against the Navy Department.

On the 13th of January, 1869, Mr. Schenck, in behalf of the select committee, reported to the House‡ a bill appropriating to Mr. Wiard the sum of $42,180.00 for nine semi-steel 50-pounders, and $83,668.49 for various expenditures attending the preparations for, and the construction of, two 15-in. guns, making a total of $125,848.49. Through the personal representations of Mr. Schenck this bill was passed by the House, and went to the Senate, where Mr. Howard, the chairman of the select committee, urged its passage. Fortunately, Mr. Grimes of the Naval committee happened to be aware of the true nature of the scheme and at his request the bill was defeated.

We have been permitted to see the original of the following letter, to the genuineness of which we can certify. We withhold the name of the firm to which it is addressed out of deference to their desire to avoid a publicity nowise agreeable to them. At the same time they are ready to make any acknowledgments which public interest may require.

May's Building, Room 3, cor. 7th and E, Washington, 21st June, 1869.

Gentlemen: It affords me gratification to be able to forward to you by mail a copy of the last report of the Joint Committee on Ordnance on the subject of heavy ordnance.

I do not know how far you have made yourselves acquainted personally with the theories I have advanced for the past eight years, in relation to the "ordnance problem." I therefore, also forward to you a copy of a communication I made to the committee on the conduct of the war, early in 1865, believing that you cannot fail to appreciate the renewed consequence, which attaches to the subject, by the determination of the fact, that 1,915 large guns are required for the fortifications, according to the report of the Board of Ordnance Artillery and Engineer officers, approved 20th of February, 1867, concluded, as shown on page 171 of the report of the Ordnance Committee; and in view of the facts, that the Rodman system is now condemned by the appropriating branch of the Government, the Parrott system being no longer in competition, and the Dahlgren gun obsolete, on account of the changes in the means of defense adopted in all countries, I flatter myself that my views on this subject are in the ascendant.

While the Rodman patents were operative (they expired last year), the money interest, with which they were sustained, could overwhelm me. Now feeling confident that I possess the only practical manner of making large guns, and that it is secured to me unassailably by patents, issued or to be issued, I hold that I have achieved a monopoly of the gun business of the future, according to law, and if any of those parties, who have heretofore opposed me in the interests of the Rodman patents—now that those patents have expired—should continue their attentions in a revengeful spirit, I have only to invoke the majesty of the law and they will be removed. As evidence of this, I forward a third publication, to which I ask your attention.

And now the real object of this letter: I am about to enter upon the gun business, either by building a foundry in Washington, or by making an arrangement with some of the already established foundries, for the production of guns upon my new system, and I desire to know if this fact interests you in any degree. I have no idea that I could impress you favorably with my plans, otherwise than at a personal interview, which I should be glad to promote, if I should learn that you were desirous of participating in it—not otherwise.

If you have any doubt of my skill, persistence, or integrity, or security—and I know there have been some reasons for doubt spread abroad—I desire to refer to Mr. Sam. Sinclair, of New York City, a gentleman who has known me well for many years. Mr. Sinclair is publisher* of the Tribune.

Hoping you will respond to this,

I am, Gentlemen,

Yours &c.

Norman Wiard.

It is certainly a most unpleasant task to us, dealing in such personalities; but we have no alternative. A great congressional committee has paraded Guy Fawkes before Congress and the country, and we are bound to hurl missiles at the effigy—or to borrow a stronger phrase from Macaulay, "the attempt to enshrine this carrion has compelled us to gibbet it."

The reader of the Eclectic will now be able to form some conception of the mockery of that investigation. It was an additional refinement of injustice, over and above that, in which Mr. Arrick figured so extensively. In that one Mr. Butler kept up the outward form of an investigating committee; but in this Mr. Wiard filled the chair, prepared the questions, catechized Admiral Dahlgren, Gen. Rodman, Col. Laidley and finally himself. The situation of the two former officers forcibly recalls the description in the Pilgrim's Progress of the trial of poor Faith-

* Id.

† Reading as follows: "I hereby accept the above as a final settlement of all claims against the Navy Department."

‡ Fortieth Congress, 3d Session House Report, No. 6.

* Which will account for the periodic onslaughts of that journal upon the Ordnance Department.

ful before Lord Hategood and the jury of personified vices at Vanity Fair.

"JUDGE.—Thou runagate, heretic, and traitor hast thou heard what these honest gentlemen have witnessed against thee ?

"FAITHFUL.—May I speak a few words in my own defense ?

"JUDGE. — Sirrah sirrah ! thou deservest to live no longer but to be slain immediately upon the place; yet that all men may see our gentleness to thee, let us hear what thou, vile runagate, hast to say."

We are not prepared to assert positively that Mr. Wiard drafted the report, because we have no direct proof; but judging from internal evidence we entertain little doubt of it. That, however, is scarcely material. The report is all he could have wished it to be. It condemns every system of ordnance except his—denounces in most opprobrious terms the Ordnance Department and its system of artillary, and recommends its abolition, and the substitution of a mixed board of officers and civilians. We do not see what he could have desired to add, unless it be the appropriation of a large sum of money for his own benefit, which the committee sought to effect in a more efficacious way by a separate report.

We have entered more deeply into the personal details of this business than was agreeable to us, because we have felt that in exposing the characters of these men we are enlightening the mechanics and engineers of the country as to the animus of the committee. In their individual capacity we are desirous to avoid all contact with Messrs. Arrick and Wiard: they are formidable only through their connexion with the committee. Since the committee placed its high authority unreservedly into the hands of these men, with no restriction as to its use, and making it merely a cover for whatever they chose to say, we are bound to show the characters of the men who were the recipients of this confidence. The real committee was Messrs. Arrick and Wiard, and the lawful committee stepped in only to give the investigations of these two men the weight and sanctity of its official character.

We feel that it is not for us to assault formally the characters of Senators and Representatives further than to state facts. The inferences we shall leave to the readers. Here are two reports—the first, written by Mr. Arrick, vituperating the Chief of Ordnance for no alleged and no conceivable reason except that he declined to make the Eureka the standard rifle projectile "to the exclusion of every other known device as worse than worthless;"—the other, written (in all human probability) by Mr. Wiard, vilifying the whole Ordnance Department, because it equally rejects his grotesque cannon. And yet, after the form of an investigation, the committee adopts them in all their grossness and in all their *ex parte* character—recognizes their serious consequences, as involving an entire change of the management of the ordnance service, and a substitution of the material of these adventurers for that already in vogue. If it be said that the committee may have been deceived, and led to espouse the cause of these men through artful misrepresentations, then the reader may ask himself, what right had they to be deceived, when they were so explicitly charged by Congress to ascertain facts and report them ? What right had they to base an opinion of a considerable and honorable body of officers, upon the sole representations of their bitterest enemies ?

We cannot close without adverting to the recommendation that the Ordnance Corps be abolished. That is a matter for Congress to decide, and any decision which may be made by that body, after a full and impartial investigation, and when it is in a position to comprehend and appreciate the subject in all its bearings, will be most cheerfully acquiesced in by the officers affected by it. Probably no corps of public officials could so well bear to be thrown upon their own resources, or is better qualified to meet the exigencies of an entire and forcible change of profession. But an honorable discharge from the service is one thing, and being kicked out for refusing to facilitate the various schemes of plunder set on foot by the Arricks and Wiards of the Washington lobby is quite another. The charges of incompetency, of the "lack of the incentive to exertion and improvement, which stimulates men not in the Government employ," the "attchment to routine," "jealousy of innovation and new ideas," "discouraging the inventive talent of the country," and the "improper and oppressive treatment of persons, who have sought to call their attention to what were supposed to be vital principles of the art" etc., etc. will pass for what they are worth. They mean simply that the Department could not appreciate the "new ideas," the "inventive talent," the "vital principles of the art," involved in Mr. Wiard's "Munchausen Artillery."

That a strong pressure will be brought to bear upon Congress, the coming winter, to abolish the Ordnance Department, or merge it into the artillery, we readily foresee. We are not disposed to make any plea for its continuance, except on the ground of public expediency. It is certain that there must be a class of officials, either military or civil, whose special functions must be the administration of ordnance duties and the provision of ordnance material. It is for Congress to judge whether these functions will be best fulfilled by civilians, or by the military; by officers specially educated for it and of protracted experience, or by officers without experience. The term ordnance is suggestive of guns; but in reality involves a whole world of executive details. It comprises manufactures, a knowledge of business, of fabrics, and of construction, far more extended than any mere trade or class of trades. Its officers are *entrepreneurs* between civilian supply and military consumption, and to be efficient and economical—to insure to the Government an equality in bargains and protection against fraud, to regulate supply by the demands of the service and to systematize the means and methods of supply, must be men who are thoroughly acquainted with the mechanic arts, the trades, the details of ordinary business, and the routine of military service. These duties must be discharged by a body of specially qualified men or the abolition of the present Ordnance Department will merely render necessary the construction of another. It would be a change of persons and not of system.

We are tempted to make one remark which we hope some Congressman will see and make a note of. If the Ordnance Department is worth anything, it ought to have the confidence of both Congress and the people. But if its recommendations are to be disregarded, its aims and purposes defeated, and its chief and his subordinates arraigned and thrown upon their defense every time an over sanguine inventor or unprincipled adventurer chooses to impeach them, then it is high time to abolish it. Like every other subordinate branch it derives its efficiency and capacity for usefulness from the confidence of the Government.

A comparison between the merits of the American Ordnance and foreign may be made briefly. As yet American Ordnance contains no *established* system but the Rodman Army, and the Dahlgren Navy, guns. The large calibers are all smooth bores. The few rifles, which have been subjected to experiment, have not given such results as to warrant their adoption;—partly because the trials, which have been made, have not accurately tested the proposed system, and partly because the trials have been exceedingly meagre*: nothing is predicted for them, but much is hoped. As for the large smooth bores, they have hitherto sustained every test, and no one of them, in the army at least, has ever burst, except after a good and sufficient measure of endurance. For the Navy we are unable to speak. During the war the Parrott rifles were extensively used. A considerable number of these burst, although the general performance of them —all things considered —was wonderfully good. These guns may be considered either good or bad, according to the standard by which they are judged. If a perfect gun be demanded, a gun which will never burst, no matter what the caliber, or the charge of powder used, then the Parrot gun was a failure. But if there be demanded as good a gun as could be built at a practicable cost, and with reasonable celerity, and which would endure, in nineteen cases out of twenty, a liberal amount of service, the Parrott gun was eminently a success. During the late war there was no large rifle in existence to be compared with it. If the carping critic chooses to point to its failures, instead of its good service, the reply is easy. It was by an immense interval the best gun of its class at that time, and it remains to be seen how much improvement has been made, since 1865, in the construction of heavy rifled artillery. That better guns have been made in England and Prussia is admitted; but whether they can be furnished in quantity, of a guaranteed endurance, and at a practicable cost is not yet fully decided. The Parrott† rifle has been adopted only provisionally until a better system can be established.

Turning to European Ordnance, we find everything in a transition state. The colossal works of Krupp, at Essen, have produced enormous rifles, which have been fired with heavy charges about 400 times, and more recently the Fraser gun has given re-

* Of the heavy Rodman rifles only three have been put to proof. One 12-in. rifle was fired 470 times before bursting; one 8-in. rifle fired 1,080 times and one 8-in. rifle 80 times.

† The country owes much to Mr. Parrott. His services have proved far more valuable than those for which Sir W. Armstrong was knighted.

sults, which are certainly promising, having sustained over a thousand fires with charges of great strength. But no European Government entertains, as yet, the least notion of adopting any one of the many systems undergoing tests, until these tests shall have accumulated so as to place the endurance of the guns beyond the possibility of a doubt. Any other course would involve a most unwarrantable risk. The enormous cost of such guns would render their definitive adoption a matter of as much solicitude as a cabinet crisis or a *coup d'état.* In brief it is safe to say that there is no system of Ordnance in Europe, whose merits are known, or which has been accepted as a system. We have in this country the Rodman system of smooth bores, which has been tested through all calibers, except the 20 in., with results which have given, as yet, no instance of failure. If we are unable to assert that it is superior to any other, we can at least assert a tolerably accurate knowledge of what it is capable, which is more than can be said of any European system. The Ordnance question in this country is not between the Rodman system and a better one, but between the Rodman and three or four whose merits are not determined. Meantime, as has already been stated, American constructors are confined to the possibilities of cast-iron, and in that restricted field American Ordnance is far beyond the competition of any foreign nation. Our irons are unequalled, our workmanship unexcelled, our accuracy of detail in the minutiæ of the process and the absolute certainty of our results, are as nearly perfect as it is possible to be. With the examples of England and Prussia before us, the Ordnance Department is reluctant to advise—especially at this juncture—the embarking upon that boundless ocean of expense, which seems necessary before it will be possible to arrive at an experimental determination of the superiority of wrought iron and steel cannon; and until those nations exhibit results corresponding in value to the enormous outpouring of money upon experimental guns which the last ten years has witnessed, prudence at least should admonish us to bide our time. Whatever the Krupp and Fraser guns may be, it is certain that they are not yet afloat, nor frowning from casemates: it is certain too that they will not menace us, until their builders know what they are good for. When that eventful time arrives, when other nations are prepared to adopt them and arm their batteries, afloat and ashore, with them, then, and not until then, will it be time to ask whether the Rodman system should be superseded. D.

STEAM POWER METERS.

From "Engineering."

There are probably but few of our readers who, being employers of steam power, have not at some time or another desired to ascertain with exactness the total amount of work done by an engine in a given time when running with a variable load, and who have not been struck by the difficulty which exists in obtaining such information by any ordinary means. So long as the work performed by an engine is tolerably constant, indicator diagrams taken at frequent intervals, and carefully worked out, will give the desired information with sufficient accuracy for most practical purposes; but, except in the case of pumping or blowing engines, the work done by an engine is seldom really constant for more than a very few minutes together, and the consequence is that ordinary indicator diagrams, unless taken in rapid succession and in considerable numbers, do not afford data from which the total power developed in a given time can be calculated with any degree of accuracy. Moreover, the working out of a large number of indicator diagrams is a tedious task, and requires a considerable expenditure of time even if the assistance of a planimeter is available, and it thus but rarely happens that an attempt is made to ascertain with exactness the power developed by an engine doing variable work.

To facilitate the taking of a number of consecutive indicator diagrams, Mr.—now Sir Daniel—Gooch, many years ago employed, on the Great Western Railway, his continuous indicator, in which the diagrams were traced by the pencil on a continuously moving strip of paper: a plan which obviated some of the difficulties of the case, but which in no way diminished the labor requisite to obtain from the diagrams a knowledge of the power which the engine had been exerting. More recently also, Mr. Arthur Rigg, of Chester, has proposed and used a form of continuous indicator, which, although possessing one or two minor advantages over Mr. Gooch's, appears to us to be open to far more serious objections than the latter. According to Mr. Rigg's plan the cylinder of the indicator is placed in communication with the engine cylinder at brief intervals, the communication being allowed to remain open for, say, three revolutions out of every hundred; while the pencil carried by the piston-rod of the indicator bears against a strip of paper, which has a slow motion imparted to it by convenient means. The effect of this arrangement is that during the time that the communication between the engine and indicator cylinders is shut off, the pencil of the indicator will trace an atmospheric line on the paper; but when the communication is open it will rise and fall tracing on the paper vertical lines, which by their length indicate the maximum steam pressure and vacuum in the cylinder. These data being registered, it is intended to calculate the power developed by the engine by working out indicator cards taken from the latter, and having maximum steam pressures and vacuums equal to those registered by the continuous indicator. This method is in any case a very roundabout one; but in instances where the boiler pressure is constant, or nearly so, and the speed of the engine is controlled solely by the throttle valve, it may be possible by some considerable expenditure of time and trouble to obtain by Mr. Rigg's plan a tolerable approximation to the power developed by an engine in a given time. So soon, however, as we have to deal with an engine having varying expansion, Mr. Rigg's system becomes useless, as it is evident that of two diagrams, both showing the same maximum steam pressure and vacuum, the one may, from an alteration in the point of cut-off, correspond to the development of twice or three times the power shown by the other. Under these circumstances the maximum pressures and vacuums registered by Mr. Rigg's instrument would, of course, be of no use whatever.

In the case of engines fitted with Messrs. Farey and Donkin's arrangement for measuring the amount of heat passing away in the condensing water, the power developed in a given time can, as we explained in a recent number (*vide* page 341 of our last volume), be ascertained with a great degree of accuracy soon as the "constant" of the engine is known—the power developed and the quantity of heat passing away being sensibly proportionate to each other. But even with Messrs. Farey and Donkin's system some calculation is requisite, and although as an accurate test of the performance of steam engines it may be considered practically perfect, it does not form a ready means, easily applicable in all cases, of ascertaining the total work done in a given time by any engine, however variable that work may be.

The only instrument yet brought under our notice which satisfactorily fulfills this much to be desired end, is the steam power meter and continuous indicator lately designed by Messrs. Ashton and Storey, of Manchester, and which to our minds was the most interesting scientific novelty exhibited at the recent show of the Royal Agricultural Society. In this apparatus a modification of the inte-grating arrangement employed in General Morin's well-known dynamometer has been used to multiply the motion of the piston by the pressure exerted upon it, the result, expressed in foot-pounds, being by suitable mechanism indicated upon a dial. The general arrangement of this ingenious instrument is shown by the engraving which we publish in the present number, and we trust that the explanation of its construction there given will render its action clear. We believe that this instrument will be found to render material aid in estimating the economical value of different engines under various circumstances, and it will at once show whether any unusual expenditure of fuel is due to increased work thrown upon the engine or to carelessness upon the part of the attendants. It will also enable the user of the steam engine to ascertain, by mere inspection of the dial, the power required to drive different machines, or the efficiency of different lubricators, and it will furnish a variety of similar information, the value of which will be fully recognized by those who have hitherto only been able to obtain it by a considerable expenditure of time and trouble. Altogether we regard Messrs. Ashton and Storey's invention with much interest, and we shall carefully watch its progress. We shall be especially glad to know that it can be used on locomotives without the vibration giving rise to defective indications, and we trust that but a short time will be allowed to elapse before it is fairly tried under such circumstances. Once let it be proved that Messrs. Ashton and Storey's steam power meter can be depended upon to register accurately the actual work done by a locomotive during any given run, and those of our railway engineers who are inclined to make experiments, will have plenty of useful work on their hands for some time to come.

DESIGNOLLE'S NEW POWDER.

By A. Payen.

From "Bulletin de la Société d'Encouragement," through Polyt. Journal.

The introduction of the breech-loading ordnance and arms is a great progress in the art of warfare. But it is not less important to improve the moving agents and the moving power for projectiles, and to invent new kinds of gun-powder, the action and energy of which might answer the various wants of modern artillery.

The importance of this question was fully understood by Designolle, who, after incessant experimenting for seven years, seems to have arrived at its practical solution. In considering the actual condition of artillery it is evident that four principal kinds of powder are required:

1. Gun-powder.
2. A quick-acting powder for short-bore cannons.
3. A slow-acting powder for long-bore cannons.
4. A blasting-powder for torpedoes and exploding projectiles.

The ballistic power of the powder used heretofore, cannot be increased by altering the mixing proportions of its constituents.

The initial velocity imparted to the projectiles by the ordinary black gun-powder has been somewhat increased by the improvement of the machinery, by which the materials are prepared and mixed in the manufacture. This has been effected especially by the use of grinding-mills instead of stamping-mills. But the explosive or blasting power, which is injurious to fire-arms, has been increased by this change much more than the shooting-power.

The principal advantage of Designolle's system of powder-manufacture consists in the possibility of producing a whole range of different kinds of powder, varying in strength, and designated by different numbers, from 1 to 10, according to their strength. Also two entirely different classes of powder can be made by this system, a blasting-powder, the strongest kind of which is ten times more powerful than an equal weight of the powder now in use, and a gun-powder whose shooting-power is equal to that of the ordinary black powder, its explosive and destructive effect being however considerably less than that of the latter.

As either of these two classes contains ten numbers, differing in strength, it is evident that the system can answer any requisition.

Designolle has solved the problem of manufacturing a powder, the different kinds of which are suitable for different lengths and diameters of the bore of fire-arms and for different weights of the projectiles, and imparting to the projectiles an initial velocity as desired and as determined beforehand.

One principal constituent of Designolle's powder is picrate of potassium. The blasting-powder contains besides this only nitrate of potassium. The gun-powder is a mixture of picrate of potassium, nitrate of potassium and charcoal. These substances are mixed in different proportions, according to the strength required.

Picrate of potassium is composed of picric acid and potassa. Picric acid is a substance which was first discovered by Haussmann, in 1788. Welter afterwards obtained it by treating silk with nitric acid. A number of French and German chemists have made researches on the same substance. But it was reserved to Laurent to find out its exact composition and chemical formula, and to discover the most proper way of making it. He showed that the picric acid corresponds in its composition to phenylic acid, in which three equivalents of hydrogen are replaced by three equivalents of hyponitric acid.

$$\text{Formula: } C^{12} \left\{ \frac{H^2}{(N\,O^4)^3} \right\} O$$

A Paris gas company produces on a large scale phenylic acid which is the principal raw material for the manufacture of picric acid and of its compounds.

Picrate of potassium is a crystalline compound, consisting of small, glossy, yellow prisms of the dimetric system. It is insoluble in alcohol, very little soluble in cold water; but it can be dissolved in 14 parts of boiling water. When heated carefully to 300 degrees Celsi, it becomes orange. It, however, retakes its original color in cooling. When heated to 310° C. it explodes with vehemence.

This substance was very dear until lately, when John Casthellaz, one of the best French manufacturers of chemicals, improved its manufacture to such a degree, and produced it at such a low cost that the price of Designolle's new powder is but very little higher than that of the ordinary black gun-powder. To be able to determine the quantity of saltpeter and charcoal to be mixed with the picrate of potassium, it was necessary to examine the chemical reaction which takes place when this substance is made to explode. Designolle found, by numerous experiments, that two entirely different reactions can take place according to the circumstances under which the substance explodes.

1. When picrate of potassium explodes in the free atmosphere, prussic acid and nitric oxyde are formed.

2. When picrate of potassium explodes in a narrow place, as for instance in the bore of a gun. neither prussic acid nor nitric oxyde are formed, but the products are in this case: nitrogen, carbonic acid, hydrogen, oxygen, carbonate of potassium and carbon.

The formula which expresses the latter reaction, and on which the manufacture of the powder is founded, is as follows:

$$KO + C^{12} \left\{ \frac{H^2}{(NO^4)^3} = 3N + 5CO^2 + 2H + O + KO, CO^2 + 6C. \right.$$

Designolle's powder is made in the following manner. The different substances are at first mixed with 6 to 14 per cent of water, and crushed fine in a stamping-mill. Three to six hours are required for this operation. The mixture is then compressed in a hydraulic press. As the rapidity with which the powder burns or explodes is in an inverse ratio to the pressure to which it has been subjected, this pressure is taken differently, according to the different use to be made of the powder under treatment. This pressure varies from 30,000 to 100,000 kilograms. The compressed mass is corned by a special machine, sifted, polished and dried. The last two operations are done in the same way as with ordinary black powder.

There is, with the above exception, no difference in the mode of manufacture of the various classes and kinds of Designolle's powder. The proportions of the materials only are different according to the qualities that are required for the different kinds. The greater the amount of picrate of potassium in the mixture, the greater is the ballistic power of the product. Gun-powder ought not to contain over 20 per cent of the picrate. From 8 to 15 per cent of it are used for making cannon-powder, the exact quantity depending on the rapidity and vehemence with which the powder is expected to explode.

The advantages which Designolle's powder has over the ordinary gun and blasting-powder are the following:

1. Its ballistic or shooting-power can be increased without increasing its explosive force.

2. The strength of the powder can be exactly regulated within the limits given by the numbers 1 and 10.

3. The rapidity of action of the powder can also be exactly regulated.

4. The ballistic power of the powder can be increased without altering the mode of manufacture and in using similar materials.

5. The effects of the new powder are very regular and uniform. The initial velocity of the projectiles thrown by one kind of this powder is always the same. This velocity varies with different kinds from 1 to almost 2 meters, according to the mixture and pressure employed in the manufacture.

6. The new powder does not contain any sulphur, so that no vapors of sulphide of potassium or of sulphide of hydrogen are produced by its combustion, which vapors are very injurious to the health of the men when working in a casemate or in the interior of a man-of-war.

7. From the same reason the new powder has no injurious effect on iron, copper or brass.

8. The smoke produced by the combustion of the new powder is but very slight, and is in fact nothing but steam with small quantities of carbonate and oxyde of potassium.

Large quantities of Designolle's powder are actually manufactured in the French Imperial cannon-foundry at Bouchet; gunpowder as well as quick and slow-acting cannon-powder, and blasting-powder for torpedoes and for explosive projectiles. S.

METALLIC TUBES.—A new and promising industry is announced, that of the manufacture of metallic tubes from rolled plates, by machinery. The resources of the tube drawer have not been called into requisition for the production of stove pipes or speaking tubes, nor is it perhaps necessary that they should be. Heretofore they have been made cheaply by hand. We shall next week illustrate and describe a simple continuous machine whereby these and other varieties of tubes may be made, at almost insignificant cost for attendance, at the rate of sixty feet per minute. They are made from flat strips or skelps, with a continuous, longitudinal joint, wherein two continuous edges are lapped and locked together by pressure only. If the statements of the patentees may be fully relied upon, small (1-inch) copper tubes made upon this plan have withstood a pressure of 250 lbs. per square inch without leaking, and tubes of iron, zinc, tin, &c., considerable although less pressures. The joint can be formed either inside or outside of the tube, so as to present a flushed surface on either side as required.

Supposing such results to be fully established by continued practice, it is a question whether surface-condenser tubes could not be made with advantage by the same process. Some of the larger surface condensers, as those of the Hercules, have upwards of twenty miles of small, say, three-quarter-inch tubing. The pressure within them, where the steam is admitted to the outside, does not probably much exceed 25 lbs. per square inch, say 12½ lbs. due to the vacuum, 5½ lbs. for the head of sea-water above the condenser, and 7 lbs. for the force required to pump through the circulating water. Should there be the least leak at any point, the leakage would be of sea-water, charged, of course, with whatever air might be in mixture with it. It is a nice question, only to be settled by experiment, whether there would be any leakage, in tubes thus made by machinery, and subjected to a pressure of 25 lbs., and, if so, whether the leakage would be such as to materially vitiate the vacuum. If a tube should leak, it is not only a difficult matter to replace it, but it is even more difficult to find it among from 3,000 to 7,000 others. So far as a little leakage of salt water is concerned, it is by no means objectionable when it is considered that a little salt water is the very thing wanted at intervals in boilers working with surface condensers. If the salt water does not enter the condenser, it has now and then to be pumped in from the sea. In the latter case, however, the supply is known, and under control, while in the former it may be anything or nothing.

If mechanically jointed tubes should be found available for surface condensers, as possibly they may be, it will be urged that the laps of the joints represent so much excess or waste of metal, and that the rolled metal, with which the process commences, must cost more than the cast metal employed by the tube drawer. It will remain to be seen how much thinner metal may be employed in rolled plates than that to which tubes of the same strength may be drawn, and there is again to be considered the great economy of manufacture in the new process as compared with the slow and tedious process of drawing. We intend to offer no opinion upon these points, but to await the results of careful experiment, results which will probably be soon forthcoming. The members of the Institution of Mechanical Engineers are likely, we understand, to have an opportunity of seeing the machine at work during the approaching meeting at Newcastle, and we shall, as we have said, illustrate and describe it in our next number. It is the invention of an American, and is being introduced into England by Mr. T. F. Taylor, of No. 9 Doughty-street, Mecklenburgh-square, and 42 Kirby-street, Hatton-garden.—*Engineering.*

THE HIGHWAYS OF NATIONS.

From "The Engineer."

With the introduction of steam, and its application to locomotives and marine engines, came the race between land and water, which should constitute the principal routes of international communication. So far as the actual distance between any two emporiums of traffic and commerce is concerned, the land has the advantage of the water in the ratio of three to one. In other words, a journey by land of three hundred miles could be accomplished by rail in the same time as one of a hundred miles by water, even supposing our fastest ocean going steamers performed the voyage. The odds are still further increased in favor of land journeys if we take into consideration the general disinclination of passengers to sea voyages, and the troubles, delays, and anxieties that are the inevitable accompaniments of those that "go down to the sea in ships." These objections do not apply with the same force to the transport of merchandise, but they are not completely invalid even in that instanee. The difference between ocean highways and similar inland routes may be briefly expressed by saying that by the former we go round the world, by the latter we go across it. A glance at the map of our own little island is sufficient to demonstrate this fact, but to appreciate it fully, and to apply the simile upon a scale of magnitude commensurate with our title, we must lay before us the railway maps of Asia and America. There we see lines stretching from coast to coast, traversing deserts, forests, and prairies, and uniting opposite seas by a medium of communication not their own. In India, the port of Beypoor, on the west, is linked to that of Madras, on the east, by a railway which runs right across the southern portion of our oriental peninsula, and Bombay and Calcutta, the city of palaces, will soon be *en rapport* by the same means. But these, and other great national arteries of commerce and civilization, sink into comparative insignificance before the gigantic chain which now stretches from New York to San Francisco. If the status of our own country reached its climax almost before the introduction of what are now recognized as the pioneers of civilization, what must be the future of the new world where the same advantages have throughout the greater portion of its vast extent preceded the advent of the population?

To unite country to country, nation to nation, and continent to continent, by a more intimate link than ever previously existed, is the mission of the age; and insomuch as the common interests of the last exceed those of the former, so much the greater is the merit due to the accomplishment of the union. As an example of our meaning, the Mont Cenis tunnel will effect the union of France and Italy, and, without indulging in metaphor, undermine the glory of both Hannibal and Napoleon. But this is but a link, locally considered, between two adjacent countries, whereas the piercing of the Isthmus of Suez accomplishes a more direct communication between Asia and Europe than the two continents have ever previously enjoyed, and constitutes in every sense a highway of nations. It might be supposed that those ports and towns forming the termini of a route of this nature would benefit more largely than others situated more remotely from its vicinity. To some extent this supposition is correct, but not to the degree usually assumed. It is impossible at the present time for one nation to become rich at the expense of another, or to benefit exclusively by the magnitude of its imports. The days of national monopoly are gone, never to return. Increase of imports signifies increase of exports, and it is only now by an interchange of traffic and commercial relations that a country can hope for a prosperous future. Projected, advocated, and carried out by a Frenchman, it would be but a fair return for his nation to reap the most substantial advantages from the maratime canal. May it be so, the more especially as we are perfectly convinced that any stimulus and increase that may be given to the trade of our neighbors will not fail to be nearly equally valuable to ourselves. At the same time it is well not to be over confident. Disappointment is ever in direct proportion to expectation. Will the hopes of our Gallic friends be fully realized?—Will the results equal their anticipations? Will the opening of the new route restore to the old "highways" their former traffic? Shall Venice rise to her pristine glory, where she "sits enthroned upon her hundred isles?" Shall the lion of St. Mark again be the lord of the Adriatic? and shall the merchandise of India and Asia be wafted to the ports of the Mediterranean?

In former times a sailor who had doubled the Cape was regarded as a tried navigator, and considered competent to give his opinion and hold his own views with his nautical *confrères*. The scientific manner in which vessels are handled at the present day, and the large increase of steamers, have in some measure destroyed the value of the old test, but still rough weather is generally looked out for near that locality. Practically speaking, the value of the Suez Canal to the sailor is that, if successful, it will obviate the necessity of the passage round the Cape of Good Hope, and reduce the length of the voyage nearly one-half. The junction of two seas that is effected by the Suez Canal has long been endeavored to be accomplished in the regions of the new world. No less than seven different lines of canal have been projected and roughly surveyed in order to discover a highway between the Atlantic and Pacific Oceans. The value of such a work did not escape the penetration of the great adventurer and discoverer Hernandez Cortes, but from his time until now, with the exception of a railroad across the Isthmus of Panama, the communication has remained *in statu quo*. A ship canal in this situation would open a new route to Australia, China, Japan, and the adjacent countries—would do away with the passage round Cape Horn, and be an invaluable benefit to the commerce of the two hemispheres. At present it appears to be an impossibility to construct this important channel without the intervention of several locks. These would be fatal to the enterprise, as to attempt to pass the traffic of the world through a number of locks is an absurdity which the most reckless speculator could not ignore. Important as some of the routes are to which we have briefly alluded, they are nothing to those which remain to be opened up. China is still a country where the "iron horse" has never run. The boundless plains of Thibet and the wilds of Tartary, in their almost immeasurable expanse, are ignorant of steam locomotion. The great Asiatic highroads have yet to be delineated by lines of iron; the caravan must be replaced by the railway carriage, and the canal by the engine.

CONCRETE BUILDING.

Mr. Goodwin, builder of a concrete warehouse in London, communicates to "the Builder," the following account of the structure and materials: The concrete is composed of one part of best Portland cement to seven parts of material consisting of clean Thames gravel, crushed slag and clinkers from furnaces, crushed bricks, stone chippings, oyster-shells, pottery, hard core from dust-yards, and any other hard and incombustible material I could get. We built upon an average per day about 12 in. all round the walls, grouting in with sand and cement at every fresh layer of concrete. We also put in hoop-iron bond at each floor. We could have built 18 in. per day, which is the depth of the apparatus, but I considered 12 in. quite fast enough for a building so high; though at other smaller jobs I have often built 3 ft. per day.

The building is 70 ft. by 50 ft., and 60 ft. high. It consists of basement and five floors, each floor supported by twelve iron columns. The roof is of concrete 3 in. thick, laid between tee-iron 3 ft. 6 in. apart, covered with asphalte. The thickness of walls is to the brick rule; those 70 ft., two floors 27 in., two floors 22 in., and two floors 18 in.; the 50-ft. walls are, two floors 22 in., and four floors 18 in. The cost of the walls, considering I got a great deal of the material for nothing, was under £6 per rod; or, take the whole of the building as a cube, the cost was about 3d. per foot. It is very strongly built, and as good as one of the warehouse class can be. It is now loaded with goods, every floor full, and has never shown the slightest crack or settlement. It is harder than most kinds of stone used for building purposes, and is of one solid mass from beginning to end.

As with Mr. Tall's patent apparatus (with which it was built) a perfect surface is obtained throughout, it requires only a thin coat of cement and sand to finish the walls perfectly smooth and true. I quite agree with Mr. I'Anson in his opinion "that the success of such work depends on the entire honesty of the man who does it."

I have learnt so much of concrete with this and other contracts I have taken since, that I find the greatest care must be used in choosing the material. I have made specimens of all kinds. Many persons, and amongst them builders, think if they have gravel, by adding the cement they have all that is required to make concrete. So much depends upon the gravel, that if it is not the right sort the work will cost as much as brickwork, and then never be sound. Every bit of loamy matter and dirt must be washed out thoroughly; then you must replace with clean sharp sand, about one-fourth.

Those who wish to build of concrete should only do so where the material is on the spot or very near. Clean river ballast, with a good proportion of sand, is as good a thing as we can have for Portland cement concrete. If some crushed slag or furnace clinkers can be mixed, so much the better; it is also lighter, which is a good thing in wall construction. Burnt clay is also a very good material, provided it is well burnt. Great care should be taken to sift with a fine sieve all crushed material; for, let it be what it may, dust, loamy matter, or fine sand, if it is finer than the cement itself it will dilute and kill it. I have made specimens of concrete with gravel that have become as hard as the best stock brick, and I have made others, with the same proportion of cement, that you may crush and crumble in your hands.

The concrete chapel I have just completed at Snaresbrook, in Essex, is built of the refuse of the brick-fields, mixed with sharp sand got from a good depth, there being a sewer in course of construction close by. The concrete is composed of one part cement to seven parts of material. The prime cost of the walls, including the working the apparatus, was £7 per rod. Many of the statements that have appeared in print upon concrete are not correct. It has to be borne in mind, a yard of concrete mixed dry, when wetted and put into the apparatus, falls considerably short of a yard,—at least 15 per cent. Neither does the cement make bulk, but disappears in measure, as does the water. If lumps of stone can be got, or brick burrs, or old bricks, to pack into the wall, it makes better work and cheaper. The more the cement can be displaced the better for the work and the less the cost.

Great care should be taken the cement is not too fresh, or it will cause the work to crack. It should be at least a month old before using.

The concrete villa at Addiscombe-road, Croydon, is now completed and occupied; it gives great satisfaction, and, it is said, will be the only house the rain will not penetrate in that neighborhood. The lower floors are all of concrete, and perfectly smooth and warm; there is no channel for a mouse or any creeping thing in that house, unless it take up its abode with the family.

THE SIEMENS-MARTIN PROCESS.

Abstract of a paper read by MR. RICHARD HOWSON, before the Iron and Steel Institute.

After some remarks touching the history of the mode of manufacturing cast steel by melting certain proportions of cast iron and wrought iron together, the writer proceeded to observe that it was not till 1845 that the process assumed a practicable shape. In that year Mr. Heath obtained a patent, the specification of which clearly describes how such a process may be carried out in the hearth of a reverberatory furnace. We have no record that his experiments led to commercial success; probably there were difficulties in the way. At a later date other workers came into the field, and in the hands of Mr. Attwood the manufacture has reached a fair degree of certainty and excellence, to which the use of Siemens's furnace has doubtless in a great degree contributed. Meanwhile, in France, the Messrs. Martin were prosecuting experiments in the same direction and on the same principle as described by Heath, and were successful. Their method of proceeding, however, introduced some new features, especially the use of oxides. The staple trade of their establishment at Sircuil is the manufacture of gun barrels, which they turn out of excellent quality from pig iron and puddled ball, which are both the produce of a pure African ore. The process may be simply described as follows: The pig iron is first melted on the hearth of a Siemens furnace, in weight from $\frac{1}{2}$ ton to 1 ton. The puddled ball (previously heated) is then added in quantities weighing about 1 cwt. at a time, with occasional small doses of oxide of iron of pure quality. By these means the carbon in the bath becomes gradually reduced to a low percentage, and the metal approaches to the state of wrought iron. A portion of the carbon is then restored by the addition of spiegeleisen, so as to give the steel the requisite temper, and the process is finished, and the whole is tapped off into ingot moulds. The ingots are subsequently hammered, rolled, and forged into gun barrels. The time occupied from charging the furnace to tapping out is about 11 hours, and the average proportion of cast and wrought iron will be about 2 of the former to 3 of the latter, with usually 2 or 3 per cent of oxides. At the Newport Works the experiments which have been made are very numerous. The next portion of the paper was devoted to a detailed description of the apparatus, and then went on: The rationale of the process next comes under notice, the state of the bath being judged of at different periods by means of tests which are from time to time taken out. After the pig iron is melted, the first action which takes place is the oxidation of the silicon. The fracture of the test is then white, like refined iron. As more wrought iron is added, it becomes more or less malleable, and the fracture assumes a dull, gray color, getting gradually brighter and more compact in grain, until it reaches the stage of true steel. At this point the process might be stopped, and has been stopped, with good results; but it is not always safe to do this in practice. The better plan is to proceed until the tests begin to bend and tear, and then to impart the requisite hardness by adding spiegeleisen, about 1 cwt. to the ton being usually a sufficient quantity, with brands containing 6 or 7 per cent of carbon. The experience at Newport has shown that little improvement is to be gained by deviating from the practice adopted by Messrs. Martin themselves, and it has also decided another question, viz: that the process offers little or no chance for the employment of low-priced iron. As a rule, the present brands produce the best ingots, and it is much to be regretted that Cleveland iron, except in the state of very carefully puddled bar, seems to be quite inadmissible. The author spoke favorably of the economy of the process and of the possibility of its standing the severe competition in England; and went on to notice two points of interest contingent to the process. In the first place, he said it had been found that when the bath had arrived at the soft stage, there was considerable danger in allowing it to remain any lengthened period before adding the spiegeleisen. As long as there was a sufficient amount of carbon in both, it acted as a protection to the iron against oxidation; but when it was all, or nearly all burnt away, the iron itself began to burn, as might be seen by the crystallized appearance of the fracture. It was a question, however, whether it was the free oxygen of the flame alone which produced this result. Professor Graham had shown that carbonic oxide penetrated iron with extreme facility; and specimens were shown which had been subjected to the action of carbonic oxide under a variety of conditions. They all presented the same appearance of deteriorated structure; and were all excessively brittle. Neither carbonic acid nor atmospheric air under similar conditions seemed to have the same effect; and it might be fairly assumed that this question required further examination. The other point to which he referred was a peculiar property of homogeneous iron or mild steel, which was early observed in the course of the experiments at Newport. When ordinary steel was chilled in cold water at a red heat, it hardened more or less according to the percentage of carbon it contained. When the carbon was reduced below a certain amount—about 5 per cent—it then obeyed the same law as copper. The metal when chilled became soft to the file; but, at the same time, more compact, tougher, and stronger. Specimens were exhibited to illustrate this fact; and the question was glanced at as to the probability of hereafter turning this property to useful account. The writer concluded by stating that much remained to be done in the metallurgy of iron and steel; and ventured the prediction that steel ingots for rails would yet be made at a price but little exceeding that of puddled bar, although he acknowledged that whoever undertook to do it would have to bring to the task a large stock of patience, perseverance and capital.

THE STRENGTH OF BOILERS.—It has been found, by actual experiment, that good forged iron will bear a strain of from 25 to 30 tons to the square inch of section. That is, a bar one inch square, or a plate of iron containing one inch of sectional area, will require a force of from 50,000 to 60,000 lbs. to wrench it asunder. Some years ago, a committee of the Franklin Institute of Philadelphia very thoroughly investigated this question of the strength of boil rs, and it was found that the tenacity of boiler-plate increased with the temperature up to 550°; at which point the tenacity began to diminish. At 32°, the cohesive force of a square inch of section was 56,000 lbs.; at 570°, it was 66,500 lbs.; at 720°, 55,000 lbs.; at 1,050°, 32,000 lbs.; at 1,240°, 22,000 lbs.; and at 1,317°, 9,000 lbs.

Strips of iron cut in the direction of the fiber were found to be about 6 per cent stronger than when cut across the grain. Repeated filing and welding was found to increase the tenacity of the iron, but the result of welding together different kinds of iron was not found to be favorable. The accidental overheating of a boiler was found to reduce the ultimate or maximum strength of the plates from 65,000 lbs. to 45,000 lbs. per square inch of section, and riveting the plates was found to occasion a diminution in their strength of one-third. The results of M. William Fairbairn's experiments differed somewhat from the above. He found that boiler-plate bore a tensile strain of 23 tons per square inch of section before rupture; which was reduced to 16 tons when joined together by a double row of rivets, and 13 tons, or about 30,000 lbs., when joined by a single row of rivets (2,240 lbs., are allowed here for a ton).

Mr. Fairbairn says that "plates when riveted together are reduced in strength from the fact that nearly one-third of the material is punched out for the reception of the rivets," and therefore he takes 34,000 lbs. as equal to the strength of riveted plates containing one inch of sectional area.

In casting up the bursting pressure of boilers, it is necessary that some number representing the tenacity of plates one inch thick be decided upon. Some engineers in their calculations estimate it at 34,000 lbs. while others place it as low as 25,000 and 30,000 lbs. These figures suppose the iron to be of the best quality, and the following rules suppose the workmanship of the boilers to be first-class in every particular. No rules can be given for poor materials, nor for poor workmanship. By a sectional inch or an inch of sectional area is understood a sufficient surface of boiler-plate of any thickness under 1 inch to make a thickness of 1 inch; or, in other words, suppose a boiler to be constructed of ½-in. iron, and from its end we cut off a section or hoop 1 in. long, two such sections would be equivalent in quantity of iron to one hoop 1 in. thick, for the two being each ½-in. thick would together be 1 in. thick. If the boiler was constructed of ¼-in. iron, it would require four such sections to make one an inch thick. If constructed of $\frac{3}{8}$-in. iron, 2.66 would be required, and so on for any thickness of plate. In testing the strength of iron, bars 1 in. square are used; hence, in estimating pressure on boiler-plates, sufficient surface must be taken for each thickness to equal in quantity a bar of iron 1 in. square. If we assume that single-riveted boilers will sustain a tensile strain of 34,000 lbs. per square inch of section before rupture, the strain on each superficial inch on a plate $\frac{3}{8}$-in. thick would be $\frac{3}{8}$ of 34,000, and for $\frac{1}{4}$-in. plate $\frac{1}{4}$ of 34,000, etc.—*The Locomotive.*

BETTER IRON RAILS.

We promised in a previous number some facts about the superior durability and economy of thoroughly worked iron in rails, and the practicability of obtaining good rails at a reasonable cost. The case of the Reading railway, to which we intended to refer, and the whole issue between railway managers and rail makers, is thus stated in the New York "Times."

Whenever a broken rail throws off a train or the enormous cost of maintaining permanent way is under discussion, there is a general outcry against the poor iron of modern production, and a longing for the skill, science and honesty among manufacturers that used to make rails last twenty years. Nothing can be more touching than the pious regrets of a railway manager, standing among the *debris* of rails, axles and machinery worn out in the flower of their youth, at the degeneracy of the metallurgical skill and conscience of the period. In order that the public may understand how far their risks of life and loss of dividends are due primarily to this cause, we invite their attention to the following facts and considerations.

The general rule in this country (to which there are indeed exceptions) in regard to the purchase of railway materials is simply this: buy the cheapest. First cost is the controlling and often the only question entertained. The nature of the materials and processes to be used in the manufacture of rails, for instance, are not mentioned. The buyers for some of our roads, especially new roads, never make the slightest allusion to quality, and never specify tests and inspections, but simply go about among the mills, comparing and beating down prices, and accepting the very lowest. More than one of our rail makers are to-day rolling, under protest, rails upon which they decline to put their trade-mark—rails made from the very cheapest materials, in the very meanest manner—for all that is required is that they shall stick together till they are laid. And if American makers will not roll them, Welsh makers will. The late report of the State Engineer of New York says: "American railway managers, instead of offering anything like a reasonable price for good iron rails, have made themselves notorious by establishing as standard, a brand of rails known all over the world as 'American rails,' which are confessedly bought and sold as the weakest, most impure, least worked, least durable and cheapest rails that can be produced." The State Engineer refers in confirmation of this opinion to the statement of Mr. A. S. Hewitt, United States Commissioner to the Paris Exposition, a statement not yet controverted; and to a statement of Mr. Sandberg, an English engineer of note, in the London *Times.* A leading American railway president and reformer has publicly said: "There is a fear on my part that railway companies will themselves tempt steel-makers to send a poor article by buying the cheapest—first cost only considered—*as they did with the iron-masters.*"

There is also a class of railway managers who pretend, and possibly believe, that they cannot get good iron rails—that the existing processes for cheapening iron in all stages of its manufacture render it impracticable to produce the uniform and excellent material formerly made. Now, while it is true that much poor iron is called for and sold, it is notorious that a better knowledge of chemistry and the modern improvements in machinery enable iron-masters to produce a more excellent and uniform material than ever before, as well as to reduce its cost.

These general facts are well enough known to those who have taken the trouble to inquire. But we are not confined to general facts. There are particular cases that cover the whole issue. The one we shall mention now is, fortunately, of such a character that no private interest can affect the statement or be affected by it. Early in 1868, the Reading Railway Company commenced rolling their own rails by an improved method, and some of them have already been down long enough, under the immense coal traffic of that road, to vindicate this policy. For instance, out of 9,000 tons of home-made rails, which had carried a certain traffic during the last nine months of 1868, only five tons, or one in 1,800 tons, had worn out. During the same time, and under the same traffic, out of 2,000 tons of rails made by the old process at an outside mill of good repute, about 200 tons, or one in ten, had been worn out and removed, and the indications are that the remaining 1,800 tons will be unfit for use at the end of this year. At a point in the road near Reading, where shifting from connecting lines is added to the regular tonnage, the life of rails made by the various old processes is from three to four months. Some rails only last six weeks. At this point the rails made by the new process have already been down sixteen months and are still sound, although much worn. The trouble with ordinary iron rails, as we have explained on another occasion, is that they go to pieces before they get a chance to "wear" out.

The best iron rails cost perhaps twelve to fifteen dollars per ton more than the poorest, but if they last twice or thrice as long, no railroad manager will pretend to doubt their economy. The trouble is, that some railroad managers, and especially the builders of new roads, never consider the question of durability. Nor is there any secret or difficulty in the manufacture of good iron rails. One process, which makers are sometimes forced into by low prices, is to cut up old rails, pile them together and roll them into slabs to form the head of a new rail. The remainder of the pile from which the new rail is rolled, is simply old rails cut up and laid together. Not a particle of new iron, which would greatly help the welding, is added, for that costs some six or seven dollars per ton more than old rails; and not half work enough is done on the loose bundle of iron forming the rail pile to compact it. Nothing is more certain than that such rails will go to pieces in the welds after short service. The method adopted by Mr. Coxe, of the Reading Railway Company's mill—and the same or a better one would be gladly adopted by private makers if companies would pay for it—is as follows: Some 70 per cent of old rails and 30 per cent of new iron (puddle-bar) are laid into a pile and rolled into slabs an inch thick. Nine thicknesses of these slabs are again piled, reheated and rolled into a headpiece two inches thick, which forms the top of the rail pile. The remainder of the pile is made up of seven thicknesses of the slabs before mentioned, the whole being heated and rolled into a rail.* In this way the body of the rail is twice compacted by heat and pressure, and the head, that receives the direct action of the car-wheels, is three times subjected to this condensing operation.

A rail thus made, instead of being a bundle of heterogeneous laminæ stuck together by cinder, and ready to split apart under the hammering of wheels, is a dense, compact, and comparatively homogeneous mass, which offers resistance not only to abnormal splintering, but to normal abrasion and wear, just in proportion to the work put upon it in the rolling mill. It is the perfect homogeneity of steel that enables it to outlast the best iron, even more remarkably than the best iron outlasts the poorest; and the nearer iron rails approach in structure to steel rails the longer will they last, and the less will they cost in the end.

It is time that this pitiful talk about the impossibility of getting good rails was stopped. There is no doubt that some railmakers "scamp" their work—a peculiarity of the period not confined to rail-making—but the worst of them can and will make good rails, if railway managers will give them a chance and institute suitable tests and inspections.

THE WERDER RIFLE.

Translated from "Polyt. Journal," by DARAPSKY.

The Bavarian government has proposed to the Chamber of Deputies to adopt the Werder rifle, together with the Berdan cartridge, for use in the Bavarian army, and to order for the present 100,000 of them. A Berlin military periodical contains the following description of the rifle mentioned: Werder's rifle is a breech-loader, simple in its construction and of small caliber (11 mil.).

The breech-mechanism has some resemblance to that invented by Peabody. The breech-block moves on an axle passing through to back part of the block at a right angle to the bore of the gun. When the breech-block is turned downwards, the breech opens, when turned upwards, it is closed. The Werder breech-block has a forked projection behind its axle. A concavity on the upper surface of the block receives the cartridge in loading.

The extractor has the shape of a joint-lever and takes hold of the cartridge from two opposite sides. The breech-block, in being turned down, sets the extractor in

* The pile is repeated after being reduced to $5 \times 6\frac{1}{2}$.—ED. V. M.

motion. A spring brings the latter back in its ordinary position. The striker is situated within the breech-block, and is retained there by a spiral spring, which also draws the striker back after each discharge of the rifle. A feature which distinguishes the Werder system from that of Peabody is this, that the breech closes of itself when the rifle is cocked. Before this is done, the breech is kept open by a double spring attached to the above-mentioned forked projection at the back of the breech-block. During and after the discharge of the rifle the breech is kept closed by a support on which a projection at the front part of the breech-block then rests. When this support is removed the breech opens again. This support is movable round the same axle to which the trigger is attached, its motion being however independent from that of the trigger. The motion of the support is effected by an arm which passes through the trigger-plate, and which ends in a finger situated within the trigger-guard in front of the trigger, but bent in an opposite direction.

The lock consists of the following parts: the cock, the main-spring, the trigger with the sear, and the trigger-spring. The cock moves within a slot in the back part of the breech-block. The thumb-plate is on the right side of the lock.

When the cock is being made ready for shooting, an arm connected with it and provided with a small roller, pushes the breech-block upwards, thus closing the breech.

All the axles rest on the two parallel cover-plates of the lock. The whole mechanism is contained in a quadrilateral case screwed on to the barrel. The same screw which holds the trigger-guard in place, also serves to fasten the breech-mechanism to the case.

The whole mechanism, above described, works in the following manner. When the rifle is cocked, the breech closes of itself. When the trigger is pulled, the cock acts on the striker, and the latter on the priming. After the discharge of the gun, the breech is opened by a slight forward movement of the index of the right hand. By this movement the index leaves the trigger and touches the finger of the arm connected with the support of the breech-block. The support is turned off, and the breech-block sinks down, owing to the action of the double spring attached to the forked back part of the block. Thus the breech is opened. At the same time the extractor is set in motion by its own spring, and the case of the cartridge is removed. All this is done in one moment, during the short time when the shooter takes the rifle down from his cheek. The new cartridge laid into the concavity on top of the breech-block then slides into the barrel. In cocking, the breech closes again, and the rifle is ready for shooting.

The rifle being in this condition, a pressure applied by mistake on the finger of the arm connected with the support, would not be of any consequence, because the support is then kept in place by a projection of the cock, provided for the purpose. This arrangement prevents the breech from being opened prematurely. If required, the lock can be set at rest. For the use of this rifle the following manipulations are necessary:

1. Pulling the trigger.
2. Opening the breech, which is done by a slight movement of the index.
3. Introducing the cartridge.
4. Cocking.

If it is intended to keep the breech closed after the discharge of the rifle, the finger connected with the support of the breech-block has to be left untouched.

To draw the charge, the cock must be relieved slowly and carefully. After this the trigger is pulled, the breech opens and the cartridge is thrown out of the barrel, through the action of the extractor.

To take the lock apart, the screw of the trigger-guard is removed, the breech-mechanism is lifted out of the case, the left cover plate is taken away. After this the lock is free, and the three springs and the other parts of the lock may then be removed without the use of any kind of instrument or tool. The stock of the rifle is one piece of wood, and has a rectangular recess to receive the lock. The weight of the whole rifle is $8\frac{1}{2}$ Zoll lbs. (1 lb. = $\frac{1}{2}$ kilogram). Its length is 50 inches of Rhenish measure. The rifle is provided with a sword-bayonet, and with a stairs-sight. The cartridge is pressed from copper with a central prime. It has been designed by Uttendörffer, at Nuremberg. 4.3 grams of powder are used for a shot. The projectile is partly cylindrical with two channels; it is oval in front and has a cavity behind for expansion. It weighs 22 grams. The case of the cartridge is conical. A coppered-iron plate of a somewhat larger diameter than that of the case, is soldered to it, and serves as a hold for the extractor. A ring of thick pasteboard is placed on the bottom of the case, inside. A small cup of brass containing the cap, and a small piece of brass is situated in the middle of this ring. It is to be seen from this description that this cartridge is a combination of Boxer's priming arrangement and of the American case-construction.

The Werder rifle, owing to the simplicity and ingeniousness of its construction, can be fired in rapid succession. The manipulations necessary for shooting cannot easily be more simplified and shortened by any other mechanism imaginable.

Well exercised soldiers have fired 14–15 times per minute, when they had to take the cartridges from their pouches. First-class riflemen at Amberg have fired 18 times in one minute, hitting each time the target, the latter being 4 ft. wide, 9 ft. high, and placed at a distance of 200 paces. A considerable advantage of Werder's rifle is the great facility with which the lock may be taken apart, a facility which every rifle for military purposes ought to possess. The whole construction is perfectly solid and strong, thus excluding all danger or mishap from breakages. These and other remarkable qualities of Werder's rifle and of the cartridges used with it, as well as the results of experiments made with both, are set forth in the military periodical of Berlin, all of which show that this rifle is one of superior excellence. S.

THE FIELD GUN OF THE FUTURE.

From the "Army and Navy Gazette."

Have we yet got the gun of the future—the gun that is to supersede all other weapons of its kind, which all men, be they Segmentites or Shrapnelites, followers of Boxer or believers in Armstrong, will acknowledge to be perfection, and join together in praising? The experiments in field artillery at Dartmoor have at length come to an end, and although the report of the committee is yet unpublished, not a little information respecting the results of the various trials has found its way in print. That much has been gained by these many experiments towards the solution of certain broad questions in the artillery science, there can hardly be a doubt, but that the information will, or can, be so condensed as to point out exactly what is needed for our field artillery we take leave to doubt. Even on the question of field artillery equipment for India it is difficult to arrive at anything like a definite conclusion, so many are the conflicting opinions on this head. During the recent experiments at Dartmoor, about 800 rounds were fired from their muzzle-loading bronze guns without drawback or accident of any kind whatever. The opinion of the committee, however, seems greatly in favor of a bronze field howitzer, as being a most desirable piece of ordnance for service. If we mistake not, the Indian artillery had formerly two howitzers in every field battery, and, although lighter than those now recommended, they were found to be most useful throughout all our great Eastern campaigns. The Russians have lately adopted bronze guns for their field artillery, and have also introduced a most formidable field howitzer of 6-inch caliber. The opinion of many Indian artillery officers seems to be in favor of a similar piece of ordnance being adopted in our own service, the more so as it would be attended with very little expense, there being numerous old smooth-bore bronze guns lying idle at Woolwich, which could very easily, and at a small cost, be converted into field howitzers. Whether any special recommendation on this head will be made it is impossible to say, but public opinion—that is artillery public opinion—goes far to make us think that for India the future field artillery will consist of muzzle-loading bronze 12-pounder guns, each battery having attached to it at least two formidable field howitzers of 6-inch caliber.

The science of field artillery, like that of every other military arm, is no doubt progressive, and is now in a state of transition. When infantry soldiers are armed with rifles that can hit a target the size of a man seven times out of ten at 1,000 yards, and when the men who handle those arms are gradually being trained to shoot with even greater precision, it is quite evident that field artillery must improve vastly both in the distance and exactitude with which it can do execution; otherwise every battery would be simply at the mercy of the first regiment of infantry that was pleased to make a target of the artillerymen, their horses and their guns. The experiments at Dartmoor have really proved the first preaching, so to speak, of this new artillery doctrine. The British public are very proud of their artillery, and have good reason to be so. But the said public is very much given to applaud what is, in these days at any rate, exactly the opposite of useful in artillerymen as gunners. To see field batteries galloping about, changing their front and opening fire with the most wonderful rapidity—limbering and unlimbering their guns with a quickness and a dash that seems wonderfully expert to all unmilitary men, are what the spectators delight in at reviews, and what give special correspondents occasion to praise greatly that of which they really know nothing. All this is pretty, looks well at Wimbledon or Aldershot, but it is not the real work of artillery. And this is the Dartmoor experiments, and more especially the report that will follow these experiments, must go far to dispel. Artillery ought certainly to be brought quickly into action, but once in action they ought to be in no hurry, and should remember that one round well placed is worth more than a dozen that have been fired at random. In a word, to use effectively field artillery the greatest calmness and precision is requisite. The first duty of the officer commanding a battery brought into action, is to ascertain his exact distance from the enemy. At Dartmoor many experiments as to the best means of working out this problem were made, but without any definite conclusion being arrived at. Some officers are in favor of telescopes being attached to the guns, others against the system; but there appears to be but one opinion respecting the necessity of instructing the gunners far more exactly than hitherto in the science—for it is a science —of judging distances correctly.— In a word, the Dartmoor experiments have proved that our field artillery must be exact, and that less care may be given to ensure dash, if more is given to create precision. They have also shown that we want a heavier field gun and more field howitzers than at present. In these days a campaign is finished in a week, and the times when a general could afford to halt for two or three days in order that his siege artillery might reach him, are gone forever. That, as yet, we have not the field gun required for service in these days of breech-loader rifles is very certain, and that we cannot afford to throw away the various guns we have made during the last ten years, is equally sure.— The Dartmoor experiments have at any rate taught us in what we are chiefly wanting in field artillery, and to learn this is something. But they have also shown very plainly that more deliberation, more experiments, and a considerable amount of patience are requisite before we can congratulate ourselves upon having found out the gun of the future, about which, before we begin to make it, let there, in the name of economy, be no doubt whatever. We have fallen into not a few ordnance pitfalls; let us beware lest we tumble into any more.

HYDROSTATIC STEERING APPARATUS.

From the "Mechanics' Magazine."

In designing the hydrostatic steering apparatus of H.M.S. Achilles, Admiral Inglefield has taken advantage of that great natural power which every floating vessel carries with it, viz.: the hydrostatic pressure of the water which sustains it. He thus has at his command an agent ready to be brought into action at a moment's notice. In such a vessel as H.M.S. Achilles, the pressure of the external water amounts to a load of about 8 lbs. per square inch at the level of the working cylinder, viz.: on the floor of the screw alley or the tunnel through which the screw shaft is conducted to the stern of the vessel. To move such a mass as the rudder of the Achilles against the resistance of the water when the vessel is going at 14 knots per hour requires very considerable power, and the problem to be solved was how to utilize the constant pressure of 8 lbs. per square inch, magnifying it so as to obtain sufficient force to overcome the resistance of the rudder. We will describe the manner in which this is effected by the Admiral, remarking that similar machinery may be adapted to any vessel.

A large cylinder, fitted with a piston and slide valve like that of a steam engine, is fixed horizontally in the lowest available part of the vessel. The external water is admitted to this cylinder through a Kingston valve guarded by a sluice valve. A powerful water engine is thus formed, ready to be set in action as occasion may require. Special arrangements for working the slide valve with unfailing certainty have been applied. A barrel is fixed at each end of the cylinder, and the piston rod extending on either side of the piston works in these barrels, which thus form powerful hydraulic pumps. These pumps are connected by pipes with two hydraulic cylinders fixed one on either side of the tiller on the lower deck. The rams of these cylinders are connected together by a crosshead carrying a strong steel pin entering a block, which slides in a groove attached to the under side of the tiller. Thus the tiller can traverse its full arc in either direction, while the rams move rectilinearly to and fro. The water in its course from the hydraulic pumps to the tiller cylinders passes through a valve box fitted with a regulating or directing slide. This slide is worked by a rod extending upwards to the wheel house on deck, and passing downwards to wheels on the lower decks, one of which may be on the screw alley far below the water line. The wheels are worked by hand like an ordinary steering wheel, one man moving them with ease. When the wheel is in its middle position the water is cut off from the pumps, but the two tiller cylinders communicate freely; thus the rudder is left free to right itself. By turning the wheel through one-third of a revolution either way, the water pressure is turned on to one or other of the tiller cylinders, and the rudder is put hard over to port or starboard as may be required. When the wheel is turned only half its stroke in either direction, the water is locked in the tiller cylinders, and thus the rudder is held fast in the position to which it had been brought.

It will thus be seen that one man at either of the steering wheels does what it requires generally twenty-five men to do at the ordinary steering wheel. By means of the sliding block, acted on by a hand screw on the tiller, the hydraulic apparatus can be disconnected in less than a minute, and the tiller can thus be left free to be worked in the ordinary way; but this is not necessary, for by putting the directing slide in its middle position the tiller is left quite free, and can be worked by the ordinary steering wheels and tackle, which need never be disconnected. Thus the hydraulic steering gear may either act independently, or it may be employed as a force auxiliary to the men without in any way interfering with the normal condition of the steering apparatus. It may be readily understood from the construction that the working power acts only when it is wanted. When the rudder has to be moved, the hydrostatic cylinder or water engine acts. When the rudder is fixed in any position the water engine ceases to move, but remains ready to start into action the moment it is required with its full force. Our readers will now understand the general construction of the apparatus which has been found so successful in H.M.S. Achilles. We need scarcely say that there were numerous details of construction which required great consideration in applying it. The whole apparatus, however, is extremely simple, easy of application, and not liable to derangement from accident or wear. We understand that it is cheaper than any other mechanical steering apparatus yet tried. The power which it utilizes costs nothing, and is always ready to hand for use. These points, taken in conjunction with its success in the Achilles, should be the means of opening the eyes of the Admiralty authorities to its value.

DUROMETER.—An instrument for determining the hardness of metals has been invented by a French engineer. It consists of a drill, turned by a machine of a certain and uniform strength. The instrument indicates the number of revolutions made by the drill. From this, compared with the length of the bore-hole produced, the hardness of the metal is estimated. It is said that most rails are tested in France by this instrument.—*Steierm. Industrie u. Handelsblatt.*

THE "STONEWALL" DISASTER.—The question arises, what is the use of legislation, or of government, as far as the safety of passengers is concerned, when naked candles are allowed among bales of hay, when a vessel provided with the legally required pumps can incontinently burn up, when the boats and life-preservers certified to be sufficient and in order, do not save the passengers from drowning, and when the destruction is as complete as if there had been no life saving appliances at all?

It seems simply criminal on the part of those who have the power, to allow boat after boat, and their thousands of passengers to be destroyed by fire or collision, when the whole boiler power of the vessels could, if the proper pumps, injectors, or other *means of application* existed, drown any possible fire or neutralize any possible leak.

WORKING RESULTS OBTAINED AT THE NEUBERG BESSEMER STEEL WORKS.

BY G. KAZETL.

[As the Bessemer Steel Works at Neuberg, in Styria, are known as one of the best and most carefully managed establishments of this kind, we communicate in the following the working results obtained at these works in the years 1866 to 1869, as published in Oestr.-Zeitschrift, by G. Kazetl, special manager of the Neuberg Bessemer Department.]

The manufacture of Bessemer steel was started at Neuberg in February, 1865, with one immovable Swedish converter and one revolving English converter of about 60 cwt. capacity each. It was intended from the start to use exclusively Neuberg pig-iron, and to run it from the blast-furnace into the converter without remelting.

The results obtained in the year 1865, have partly been published before this. The above tables contain the working results, beginning from 1866, since when the manufacture may be considered as being carried out regularly and steadily.

The Swedish converter was removed in the middle of the year 1866, and replaced by a second English or revolving converter of 80 cwt. capacity. The results obtained in this Swedish converter were quite or near as satisfactory as those obtained in the English vessel as regards the quantity and quality of the products and the consumption of fuel. But the amount and cost of tuyeres, bricks, and other lining materials required for the Swedish converter, were very high.

Table III, shows a very great consumption of cokes for heating the converters in the second half of the year 1866. The reason is that about this time the opinion prevailed that the heating of the converter to a high temperature, before the beginning of the charge, might be of great importance, and the experiment was made to see the effect. [It may, indeed, be seen from Table II, that during the same time the scrap produced by discharges from the vessel was considerably diminished.] In the beginning of the year 1868, the production had to be increased, and as the blast furnace was not able to furnish the required quantity of pig-iron, an additional number of charges were made with pig-iron remelted in a cupola furnace. Thus several charges could be blown in immediate succession, which circumstance lessened the consumption of heating fuel to a great extent. [The production of scrap was diminished at the same time.]

From 1866 to 1868, the steam for the Bessemer blast-engine was taken from the same boilers which furnished the steam to the blast-engines of the blast-furnaces.—These boilers being heated by the waste gases from the blast-furnaces, it was only necessary to burn some wood, in addition to the gases, to fully produce the quantity of steam required for the Bessemer engine.—Towards the end of 1868 separate boilers were put up, and were heated with bad and cheap fuel as lignite, cinders and small coal.

The increase in the consumption of lining materials, in 1869, is due to the use of a less good, but cheaper quartz. More fire-bricks were used in the last twelve months, because the cast-iron bottom plates below the moulds were replaced by frames lined with fire-brick. S.

GOVERNMENT AID TO SCIENCE.

From "The Engineer."

Two or three years ago several thousands of pounds per annum were placed by the late Government at the disposal of the Royal Society, to be expended in the establishment of meteorological observatories in different parts of the United Kingdom, in order to supply accurate daily weather reports to the Board of Trade. This step was not without its moral influence upon the scientific world, for at the British Association at Norwich last year, it was suddenly discovered that the scientific world generally was very badly off, and most decidedly in want of money aid from the Government. Lieutenant-Colonel Strange read a paper at Norwich on the subject. He acknowledged that Government aid would be certain to give rise to "jobbing" and jealousies, but urged that the good done would outweigh the evil. The opposite side of the question was then taken up by Professor Huxley, who said, with much reason, that the present free and easy way of pushing on scientific research was the best for the nation and best for philosophers. Nothing would so chill and deaden the energies of the scientific world as the transformation of any large portion of it into a Government department. The result of the conference at Norwich was the appointment of a committee of eminent philosophers to inquire whether adequate means exist for the vigorous prosecution of scientific research; and if not, what remedy should be provided.

So far everything went on swimmingly, but then a frost, a chilling frost, blighted the bright dreams of the philosophers. A new Chancellor of the Exchequer came into power, who has said "No!" many times and oft, to demands made by individuals and corporations for aid from the national coffers. He not only refused a modest demand for cash made by a Scotch scientific society, but expressed doubts whether the grant made for meteorological observations under the

Board of Trade ought to have been made.—The Government, he stated, ought to do nothing which the people are likely to do for themselves if left free to act. With the prospect looming in the future of facing a gentleman of this description, the Britith Association Committee, of course, could not very well come to the conclusion that application should be made for a Government grant, which every body a year ago thought would be the result of their deliberations.—But they have unanimously decided that scientific bodies want more funds; and what corporation of human beings does not? A direct onslaught on the nationl resources a being manifestly injudicious, they then recommended that application should be made for the appointment of a royal commission to inquire into the subject. Lieutenant-Colonel Strange read this report of the committee a few days ago at the Exeter meeting of the British Association, and he prefaced it with a doleful introduction of his own, read with the countenance of a mute at a funeral.

Many will doubtless think that a scientific journal is bound to support scientific men in all and every rush at the public purse.—Apart from the selfishness of such a line of action, and its neglect of the general interests of the nation, in this case it is no use doing so. Very recently an application of a very influential character was made to the Chancellor of the Exchequer to appoint a royal commission to inquire into the working of the Bank Charter act of 1844. This act is believed by the political economists to be the source of many commercial panics and of a vast amount of pauperism, while any banker can bear witness that it has indirectly been cause of the ruin and bankruptcy of many honestly managed banks.—Yet this application, of more importance than the one proposed to be made by the British Association, was refused on the ground of the expense of the commission, and because the action of the law upon the public is perfectly understood already by those educated in the science of political economy. Of course, once let the proposed commission on scientific needs be appointed, the result of the large amount of talk which would follow would not certainly be a recommendation of increased national expenditure. Instead of trying to obtain a few thousands of pounds annually in this way, with the certainty of failure, why do not the committee take steps to get a few tens of thousands of pounds annually from a more legitimate source? The subject of national education must soon come to the surface, and if the British Association then urged the necessity for general teaching of elementary science in schools, and the desirability of making grants to encourage this branch of education, all the members of the British Association would support the movement.—At present there is a division in the camp, and very many hold the views of Professor Huxley. If science were generally taught in schools we should soon have a population willing to subscribe largely to push on scientific research without aid from the Government. The Wesleyans have shown what enormous sums can be raised annually by private subscriptions, where large numbers of people join together in favor of any particular line of action. Those numbers may or may not be one in twenty of the total population, but is it hopeless to attempt to train up a similarly large number of people to have an interest in science? If the British Association and its president of next year were to make a dead set at the Government, insisting that the teaching of science in schools shall be a marked feature in all future educational legislation, they will succeed to a large extent, for they would carry national opinion with them. The present plan will fail, and even the intention mentioned by the President of section A, of getting up a discussion upon it before the settings of the British Association came to a close at Exeter, was abandoned.

THE SEWAGE OF TOWNS.

Abstract of a paper by Dr. BENJAMIN H. PAUL, read before the British Association.

This paper was the voluminous and valuable report of a committee on the Treatment and Utilization of Sewage. The report traced the history of sewage in England from the most primitive appliances, to the use of cess-pits, and lastly, of the present water carriage system. At the outset of the adoption of this system, it was contemplated to utilize it as manure, but was not enforced, and was now generally carried into the rivers and the sea so long as it did not create a great nuisance. The system now greatly polluted the rivers, and had become an evil of national importance. During the last thirteen years the subject had engaged the attention of three Royal Commissions. with a view to finding remedial measures, The object of this committee was to supplement the efforts of the last sanitary commission, by obtaining special information of local influences of the experience of various towns. Town sewage, as now known, was a source of nuisances and inconvenience, and was undoubtedly injurious to health, and it became a very serious matter to determine what to do with it. The committee had obtained information of the sewage on the Continent and Austria. From this they gathered that both in large towns and country places there the old system of cess-pits was still in use, and water closets were rare even in large towns. In Berlin, with its population of more than 600,000 the still more primitive and objectionable night-stools were employed, 50,000 being in use every day. This was remarkable in a country so advanced in other respects as Prussia is. Hamburg was the only continental town in which water carriage system was carried out. In other places large portable reservoirs were used, and were periodically removed outside and there emptied. In some cases the householders pay for the removal, in others it is sold to cover the cost. In Antwerp the profits of the sale is two or three thousand pounds, and in Strasbourg the sale just covers the cost. The result of this foreign information was to show that the removal of sewage so as to prevent evil consequences, was at least as much an open question as in this country, and that there was an opinion that the collection of refuse materials was injurious to health, by exhalations, and by polluting rivers and wells, and that a remedy is required. The great question was to decide as to the best mode of dealing with the town refuse so that it might be satisfactory to health and would realize its greatest agricultural value as manure without its concurrent advantages. A series of questions had been sent to 338 towns in England, and answers had been received from 107 towns, of which 11 had no sewage at all, and in others the systems adopted were very defective; 48 towns had a complete water carriage system, and 15 applied the sewage to land, previously subjecting it to treatment. The results varied considerably, the local influences at work being very different. From some towns it was said that all obnoxious matters were removed from the sewage, and that it flowed off clear as water. It was questioned, however, by chemists, whether all deleterious matters were destroyed, and whether the clarification as seen by the eye was not all the advantage gained. This sewage manure was sold from 6d. to 2s. 6d. a ton, and one town mixing it with other substances, made a manure sold for 7s. 6d. a ton. Leicester sold 5,000 tons a year. The result of this utilization of sewage had been seen in the improved condition of the streams of rivers. Little objection had been urged against the use of sewage for irrigation of land, and where objections were made they were not supported by medical authorities. The cost of these various systems, and their influences on the sanitary state of the towns, were subjects for further inquiry. The ventilation of sewers was also an important question, for in them gases were given off and found to escape through the drains of the streets and of the houses. Such questions as the value of the sewage for agricultural purposes, and the best means of collecting and preparing the manure, required further consideration, and for this purpose it was suggested that the committee should be continued.

CAISSONS.—At Rochester, England, a bridge across the Medway was commenced in 1850. The piers were made of cast-iron caissons, 7 ft. in diameter, and driven a depth of 44 ft. into the bed of the river, through gravel, sand, rocks, and the debris of an old timber bridge, built, probably, by the Romans. At first the exhaustive process was used, but was soon found to be insufficient, and the atmospheric pressure process was tried. The caissons were then driven in an unexpectedly short space of time, and at one-third the estimated cost, through the obstacles above mentioned, and that to the great surprise of all engineers. However this was not the first experiment of the kind; it had been successfully applied several years previously in France, in sinking iron caissons through quicksands, in order to reach a coal mine at a depth of 82 ft. beneath the surface, the workmen having been exposed to a pressure of three atmospheres.

In several other works the vacuum process was first tried, but soon abandoned as insufficient. They were as follows: In the year 1851, the engineer of the Rochester bridge, W. Corbitt, built the piers of the Peterboro' bridge with cast-iron caissons 6 ft. square, placed in contact and afterwards filled with masonry. In the year 1853, Major Gwynne and L. Fleming built the foundations of a bridge across the Pedee, North Carolina, with columns 6 ft. in diameter, driven a distance of 25 ft. through sand. Afterwards, they constructed the Santee bridge. In the year 1859, General Smith built the Savannah bridge. In 1860, the Third avenue bridge across the Harlem river was commenced. Brunel built a pier at Saltash with a caisson 37 ft. in diameter, sunk to a depth of 98 ft. below the water; it had the size and shape of the foundation of the entire pier, and was afterwards filled with masonry. All this was accomplished by means of atmospheric compression, and this system has, since the year 1850, met with more favor the better it has become known, until now it has become almost the universal method employed where currents are rapid and the river bed treacherous. The American experience is this, to wit: That in the Southern rivers, where cypress logs and other large objects are encountered, their removal by the exhaust system is utterly impossible, but, on the contrary, comparatively easy by means of the compressed air process which, therefore, is now exclusively used. Also, the most eminent engineers in England agree as to the utter insufficiency of the exhaust and the advantage of the plenum process. We will only mention Corbitt, Hawkshaw, Simpson, Brunel, Hemans, Brunlees, Page, Fox, Rawinson, Brereton, Fitzgibbon, Brassy, besides many continental engineers.

A caisson in which the air is driven down by means of pressure, notwithstanding it is worked on the principle of the diving-bell, is very distinct from it; because a diving-bell is a mere tool suspended from a vessel or from the shore, and used to lay foundations, etc., while the caisson forms a part of the foundation itself. The diving-bell is hoisted out, and when at the bottom is inaccessible, while in case of the caisson there is an uninterrupted communication with the outside. Our Harlem bridge contains also that improvement, which the builder, Wm. McAlpine, has termed "expansion of the base." The supporting power of the column is thereby greatly increased at a trifling cost. We will not confine ourselves to a description and illustration of English and Danish engineering works, overlooking the merits of our American engineers, whose achievements are equal in merit to those abroad. It is, however, unfortunate that they are too busy to give attention to descriptions for the benefit of the public. We will, in a following number, give a description of the process carried out in the construction of the Third avenue bridge. It is a very fine specimen of hydraulic engineering, though we cannot deny that it has two grave defects. It cost too much money, and was too long a time under way. In justice to the engineer we must, however, say that these were the faults of the political gentlemen then to be found over the way, in the City Hall, who had charge of the disbursement of the money required for its construction.—*Engineering and Mining Journal.*

PENETRATING INCLINED ARMOR.

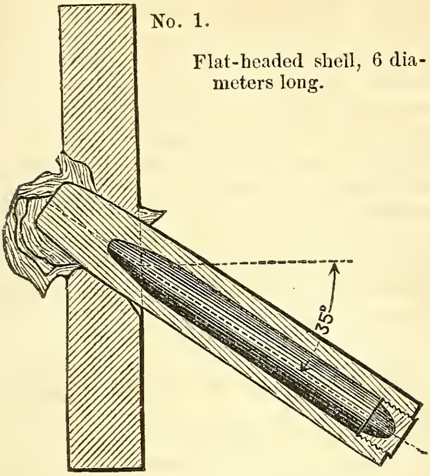
From a paper read before the British Association by JOSEPH WHITWORTH, Esq., "On the Penetration of Armor Plates with long shells of large capacity, fired obliquely."

At the meeting of the British Association at Norwich, last year, I contributed a paper to this section on "The Proper Form of Projectiles for Penetrating through Water." This paper was illustrated by diagrams showing the effect produced on an iron plate immersed in a tank of water, by projectiles with flat, hemispherical and pointed heads. Copies of those diagrams are now before you. In that paper I claimed for the flat-pointed form of projectile, made of any metal, three points of superiority over the spiral-pointed projectiles adopted in the service: (1) its power of penetrating armor plates, even when striking at extreme angles; (2) its large internal capacity for bursting charges when constructed as a shell; (3) its capability of passing undeflected through water, and of penetrating iron armor below the water-line. This latter feature was, I think, satisfactory proved by the experiments described last year, and I desire to draw the attention of the section to the experiments I have made for illustrating the penetrative power of long projectiles with the flat front, fired at extreme angles against iron plates.

These experiments are illustrated by the projectiles actually fired, and the plates they penetrate, which are laid on the table, and also by the diagrams before you.

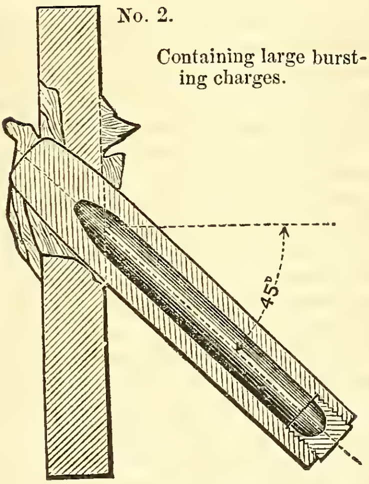
The gun from which the projectiles were fired is called a 3-pounder, though capable of firing much heavier projectiles. It weighs 315 lbs., and the maximum diameter of its bore is 1.85 in.

The charge of powder used, in all cases,



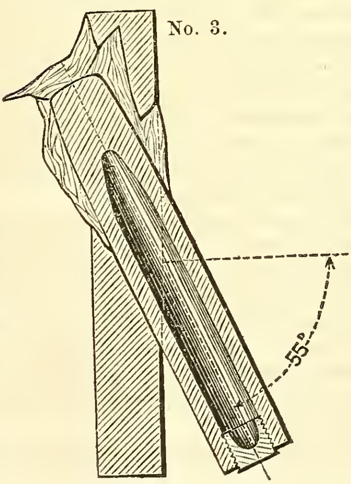
No. 1.

Flat-headed shell, 6 diameters long.

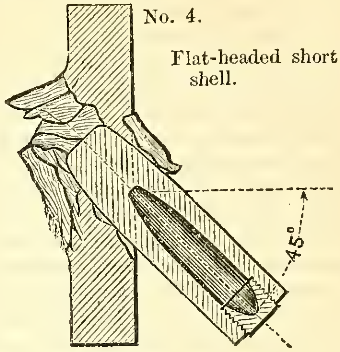


No. 2.

Containing large bursting charges.

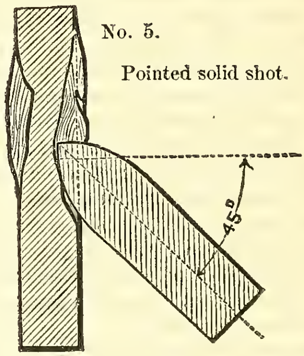


No. 3.



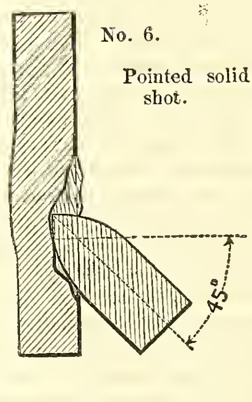
No. 4.

Flat-headed short shell.



No. 5.

Pointed solid shot.



No. 6.

Pointed solid shot.

was 10 oz., and the weight of the 6-diameter projectiles is 6 lbs.

No. 1 is a portion of a plate 2 in. thick, penetrated by the 6-diameter flat-fronted projectile also; No. 1 at an angle of 35 deg. No. 2 is a similar piece of plate, 1.7 in. thick, completely traversed at an angle of 45 deg. by the flat-fronted projectile No. 2, which buried itself to a depth of 30 in. in a backing of iron borings. No. 3 is a piece of plate 1.75 in. thick, penetrated at an angle of 65 deg. by the flat-fronted projectile No. 3. No. 4 is a plate 1.7 in. thick, nearly penetrated, at an angle of 45 deg., by the $3\frac{1}{2}$-diameter flat-fronted projectile No. 4. No. 5 is a plate $1\frac{1}{2}$ in. thick, against which the ogival-pointed projectile No. 5 was fired at an angle of 45 deg.; the projectile failed to penetrate the plate, being defected in consequence of the pointed form of the head. The distortion of its shape shows the force with which it struck the plate, and proves the good quality of the material which could resist such a test. No. 6 is a plate also $1\frac{1}{2}$ in. thick, against which an ogival-pointed projectile, of the service proportions, viz: $2\frac{1}{4}$ diameters long, made of Pontypool white iron, has been fired; the projectile has scooped out a furrow 4 in. long and $\frac{7}{10}$ in. deep; it broke up into fragments, of which 48 were recovered.

The plates Nos. 1 and 3 were purposely thicker than the projectile could quite pass through, in order that the "work" of the projectiles might be as severe as possible; an examination of the projectiles themselves will show how well they have stood the severe strain to which they have been subjected. The data thus obtained fully establish, I think, the superiority I claimed for the flat-fronted projectiles made of my metal, and satisfactorily prove—(1) that the flat-fronted form is capable of piercing armor-plates at extreme angles; (2) that the quality of the material of the shells enables their length to be increased without any risk of their breaking up on impact, and materially augments their bursting charge as shells; (3) that this increase in length, while adding to the efficiency of the projectile as a shell, in no way diminishes, but, on the contrary, proportionally improves its penetrative power; (4) that the amount of rotation I have adopted in my system of rifling is sufficient to insure the long projectiles striking "end on," and, consequently, to accumulate the whole effect of the mass on the reduced area of the flat-front.

These experiments show, further, that the ogival-pointed projectile has but small power of penetration when striking at an angle, solely on account of the form of the head; a projectile of Whitworth's metal, with the like ogival-pointed head, as a service projectile, having resisted the shock of impact without breaking up, but being deflected in precisely the same manner as the pointed service projectile, which was shivered into fragments. The objections I made in my paper last year to the ogival-pointed projectile—(1) that its form of head causes it to glance off from plane or convex surfaces when hitting diagonally; and (2) that the brittleness of its material renders it liable to break up on impact—I have now proved to the section. The facts illustrated by these experiments are not of recent discovery. Ever since 1858 I have constantly been advocating the flat front. I have on the table a small plate $\frac{1}{2}$ in. thick, experimented upon, in 1862, with hardened steel bullets fired from my small bore rifle. No. 39 is the hole made by a flat-fronted bullet, which has penetrated the plate at an angle of 45 deg.; No. 40 is the indent of hemispherical-headed; and No. 41 of an ordinary round-nosed bullet, both fired at the same angle of 45 deg. These three rounds were fired in 1862.

Within the last few days I have had an ogival-pointed shaped bullet fired at the same plate at the same angle, in order to confirm the effect with that produced, on a larger scale, on the plate No. 6. It is interesting to observe how closely the results obtained with the small caliber of my rifle agree with those of the 3-pounder gun which form the subject of this paper. Those experiments recorded in the paper were made with a gun of small caliber, from considerations of economy and convenience; but I have always found that what I could do with the smaller calibers of my system, could be reproduced in the larger sizes; and from my past experience I feel warranted in asserting that tfie effect of penetration now exhibited could be repeated, on a proportionate scale, with my 9 in. guns at Shoeburyness, or with the 11 in. guns my firm are now engaged in constructing.

A glance at the formidable nature of the projectiles thrown by these guns, and a consideration of the effects they may be expected to produce, will show the importance attaching to the question of penetration of plates by long projectiles. The 9 in. guns to which I have referred weigh fifteen tons each, and are capable of firing powder charges of 50 lbs. A 9 in. armor shell, 5 diameters long, weighs 535 lbs., and will contain a bursting charge of 25 lbs.

I have no hesitation in saying that these projectiles would pierce the side of a ship, plated with heavy armor, at a distance of 2,000 yards, and at some depth below the water-line. The 11 in. guns will weigh 27 tons, and will be capable of firing 90 lbs. powder charges. The 11 in. shells, 5 dial meters long, will weigh 965 lbs. and wil contain bursting charges of 45 lbs., and would pierce the side of the ship Hercules, plated with 9 in. armor, at a distance of 2,000 yards.

Were it not that the increased destructiveness of war must tend to shorten its duration, and diminish its frequency—thus saving human life—the invention of such projectiles could hardly be justified; but believing in the really pacific influences of the most powerful means of defense, these long projectiles I call the "anti-war" shell. The principle I have always insisted upon, and laid down for my own guidance in artillery experiments—when either a low trajectory or penetration is required—is, "that every gun should be in strength capable of withstanding the largest charge of powder that can be profitably consumed in its bore." I have drawn up the accompanying table of the sizes of the bores of my guns, with their proportionate powder charges, and the guns will all be fully equal to this duty, and I believe the greatest possible effect from the consumption of a given quantity of powder will be obtained. But the guns adopted in our naval service are not equal to such a test; nor, as I believe, are they so proportioned as to realize the best effect from the quantity of powder they consume.

Four guns of 12 in. bore have lately been put on board the Monarch. They weigh 25 tons each, and charges of 50 lbs. and 67 lbs. have been fired from them with projectiles of 600 lbs. weight. I have no doubt that these guns have been made with all possible care, and are as strong as their material and construction admits; but if the weight of these guns was in proportion to the capacity of their bore, and if the material were the best that our metallurgical skill could supply for such a purpose, they ought to fire 117 lbs. of powder, and projectiles of 1,250 lbs. weight. They would then be efficient weapons; but at present they are more formidable in name than in reality.

We are often flattered by being told that we have the best guns in the world. That may, or may not be the case. But I think that we should not rest contented while we are still so far from having attained as much as our present advancement in mechanical and metallurgical science has rendered possible for us.

Mr. Whitworth's patent cartridge increases the range from 15 to 20 per cent. JOSEPH WHITWORTH & Co.
Manchester, 1869.

GAS FROM SEWAGE—A vague report of some experiments which have been made in India, and which, it is said, have resulted in the production of gas of high illuminating power from sewage, has set numbers of people speculating on the possibility of lighting London from the same source. If this could be accomplished no modern application of science could equal it in importance. It would at once remove a nuisance and convert an enormous waste into profit, and besides that would, in London alone, save the consumption of something like 1,000,000 tons of coal a year. While we are yet in ignorance of the mode of operating which has resulted in the success reported, we can only, with the knowledge we possess, speculate on what may be accomplished by different methods of treatment. Sewage in London, now well drained and well supplied with water, means animal excretia and household refuse largely diluted with water. What sewage means in India we do not know, but, according to Sir John Thwaites, it is solid excretia. Now, the only conceivable mode of obtaining gas from such a material as solid excrement, is by distilling it in a retort just in the same way as we do coal; and, as we know the chemical composition of the excrement, it is not difficult to guess what the result of the distillation would be. It would, in fact, be a disgustingly offensive mixture, consisting probably of marsh gas, carbonic oxide, carbonic acid, ammonia, and some other nitrogenized vapors, which would give to the whole an odor to which the smell of burnt feathers would be a perfume. No doubt most of what might be considered impurities in this mixture could be removed, and the two combustibles, marsh gas and carbonic oxide, left alone. But in this case the bulk of the gas would probably be reduced by at least one-half; and the remaining half would have no value for illuminating purposes, while it would be highly poisonous. We may say, however, that although we think it highly improbable that any olefiant gas or light-giving vapor would be produced in the process, it is quite possible that some might be present if any kind of fat were found with the excretia.

So far with the treatment of the solid matters. We may consider now how gas may be obtained from sewage diluted with a small quantity of water. Placed in close vessels and allowed to ferment, the result would be the slow production of large quantities of marsh gas, carbonic acid, ammonia, and a few other gases; but, again, the gas would give no light when burnt. If lime were added to the slush, marsh gas would be obtained more rapidly, and in larger quantities, and no carbonic acid would be mixed with it. If we take sewage such as we have in London, and allow it to ferment, we again procure marsh gas; but neither in this case nor with the slush do we procure gas possessing any illuminating power. We are quite willing to confess our ignorance of any feasible means of obtaining gas from sewage but those we have mentioned above. We shall probably be laughed at by those no better informed than ourselves. Meanwhile, we shall wait for an exact account of the experiments made in India, in the expectation of learning that something more than sewage has been employed. In dismissing the matter until we get the information, it may be worth while to notice what changes the manufacture of gas from sewage in London would necessitate. In the first case we put the use of solid excretia; it would involve the entire discontinuance of our present system of house drainage, and a return to cesspools, or some equivalent for them. If concentrated sewage be used, it means a double system of drainage for every house and the whole metropolis. Lastly, if ordinary sewage be used, it has been calculated, from the results of Dr. Letheby, who analyzed the gases produced in the fermentation, that to procure the gas required for one day and night in winter it would be necessary to store, in close vessels, twelve hundred millions of gallons, or more than a fortnight's sewage, which is nearly double the quantity that all the reservoirs of all the London water companies put together would contain.

Some other considerations present themselves, which we may dismiss very briefly. In the fermentation of sewage there is no doubt that various morbid poisons are developed. The poison of fever is generally believed to be derived from this very source, and, according to some, cholera is spread by the same means. A leak in a gas-pipe might, therefore, involve worse consequences to a household than result from untrapped trains. But on this matter it is needless to speculate. We say again we wait for information.—*Mechanics' Magazine.*

SURVEYING INSTRUMENTS.

By E. Sherman Gould, C. E.

NO. I.—THE SIXTY-SIX FEET CHAIN.

The ordinary chain used in surveying is very susceptible of, and very much exposed to, both extension and contraction.

1st. It expands and contracts by heat and cold. Its expansion between the freezing and boiling points is the $\frac{1}{1000}$th part of its length, or nearly $\frac{8}{10}$th of an inch. This source of error is of course neglected in ordinary operations.

2d. It stretches very much by being tightly drawn when in use, and is shortened by the links becoming bent. This must be guarded against by frequent comparisons with an accurate standard.

If the ground to be chained were perfectly level and smooth, a very high degree of accuracy could be obtained even with the ordinary chain. But in practice it is never so. The ground is always more or less rough and undulating, and these obstructions and deviations take up a portion of the chain, and make the measurements too long. The skill in chaining consists in knowing at a glance the amount of allowance to be made from the nature of the ground chained. I should recommend in all cases that the most experienced hand should go ahead.

This is contrary to rule, but I am convinced that it secures the best chaining. The follower has only to hold firm to the pin, and keep the leader in line, while the latter must estimate the amount of chain taken up by obstacles, etc., and make the necessary allowance.

On sloping ground (which should always be chained *down hill*, even if it is necessary to chain the slope backwards) the chain must still be held horizontal. In order to do this, it is necessary, sometimes, to chain in short lengths. The late Prof. Gillespie, in his admirable treatise on surveying, gives the following excellent method of handling the chain in such cases, in the following words: "To measure down a steep hill, stretch the whole chain in line. Hold the upper end fast on the ground. Raise up the 20 or 30 link mark, so that that portion of the chain is level. Drop a plumb line or pin. Then let the follower come forward and hold down that link on this spot, and the leader hold up another short portion as before." In this way the liability to error in adding up the short measurements is avoided.

When the whole chain is held up off the ground, the catenary curve that it forms will reduce the length at least an inch, if a good stretching pull be not exercised.

Under the guidance of an experienced leader, the measurement of 30 or 40 chains, if repeated, should not show a variation of more than a link, if the ground be at all favorable. This degree of accuracy should be insisted upon in important work. Greater accuracy cannot be obtained by the ordinary process.

NO. II.—THE COMPASS.

This instrument was formerly used for even the largest and most important surveys, but is now falling into almost entire disuse, except as in the form of a pocket instrument, and for some purposes which will shortly be mentioned. With it accuracy is unattainable, except through accident. The only reason why its imperfections are not more apparent is, that as the observations, unlike those taken by the transit, are independent of each other, their errors, by the doctrine of chances, are apt to neutralize each other to a certain extent. Were it otherwise, the results would be too grossly inaccurate to permit of the use of this instrument in any case.

The great vices of the compass as an instrument of precision are,

1st. Its susceptibility to local attraction.

2d. The diurnal variation of the magnetic meridian, which amounts sometimes to as much as a quarter degree between the morning and the afternoon of the same day.

3d. The impossibility of reading the instrument with exactness, owing (*a*) to the bluntness of the indicator, or needle; (*b*) to the fact that this indicator does not come in actual contact with the graduated limb; (*c*) to its unsteadiness; (*d*) to the insufficient minuteness of the graduation of the limb, it being necessary to estimate the number of minutes, less than 30, cut by the needle.

4th. The imperfect manner in which the instrument is usually adjusted, it being very rare that two compasses will agree in the bearing of the same line.

It must be borne in mind that I am now speaking of this instrument in reference to the higher operations of surveying, where a considerable degree of accuracy is required. For ordinary purposes, such as "running around" a small farm, particularly with a view to ascertain its acreage, the compass is undoubtedly the handiest instrument that can be employed in point of rapidity in the field, and the convenient shape in which the notes are taken for office computation. For all kinds of rough and preliminary work, too, where it is desired to obtain, with but little outlay of time, an approximate estimate of the "lay" and extent of a tract of land, and for reconnoitering, it stands without a rival, for by its aid a line can be run through the woods without felling any of the trees which intercept the view, and no back sight nor base are necessary, beyond those which the magnetic meridian itself furnishes. In a word, it admits of *superficial work* in association with a sufficient degree of accuracy for approximate purposes, which instruments, like the transit and theodolite, do not. It is, when it becomes necessary to lay out or survey with accuracy a large body of land; to range long lines and turn angles, that the compass proves itself a worthless auxiliary, and loses signally its great advantage of rapidity, for the work, where checking at first has to be tediously wrought into shape by successive approximations, the first locations being merely trial lines, from which the true ones must be deduced—a work of some difficulty, since lines run with the compass can never be quite straight.

In using the compass abundant time should be given for the needle to settle. It should be borne in mind also, that the center of the compass, unlike the transit, is not necessarily directly over a certain point when a plumb line, suspended under the tripod head drops upon it, for the ball and socket of the compass is so high above the tripod head, that the centre of the instrument may be carried considerably to one side or another of the given point. In ordinary compass work, however, this is a matter of little consequence.

In running out lines with a certain bearing, the vernier may be advantageously used. Thus, to locate N. 12° 23′ E., set the vernier 23′ to the left, *i. e.*, as if for westerly variation, and run N. 12° E. by the needle.

In taking the bearing of a certain given line, the manipulation of the vernier is so tedious, that its use is generally abandoned by surveyors.

SUB-AQUATIC TUNNELS.

From "The Builder."

The anticipated success of a well-designed, though cheap and simple, tabular driftway under the bed of the Thames, has attracted a considerable share of public attention to the subject of subterranean, or subaquatic, communication. The idea of a tunnel, indeed, has been rendered so familiar to the inhabitants and to the visitors of London by the convenient service of the Metropolitan Railway, that persons who are devoid of the slightest idea of the difficulties with which the engineer has to contend, from the moment when he bids farewell to open daylight, come to speak of a tunnel as a very ordinary piece of work, and gravely discuss the feasibility of a structure of this nature, of the modest length of 30 miles, and at a level dipping some hundreds of feet beneath the bottom of the Straits of Dover.

Mr. Barlow's success, we trust, is now beyond doubt. Of the 1,320 feet demanded for his driftway, he has already safely constructed upwards of 1,000 feet; and the tube, advancing from a shaft on the northern bank of the Thames, has been pushed beyond low-water mark on the opposite shore. In his letter published a few days since, Mr. Barlow asserts that the very moderate estimate of 16,000 pounds for the entire work will not be exceeded. Should this prove to be actually the case, there can be little doubt of further demand on the skill of so economical an engineer. But the reason for which it occurs to us that it is most important that the public should not be misinformed as to the actual risks and difficulties against which the engineer of a tunnel has to provide, is as follows:

In all normal times of engineering activity, a marked and novel success, especially if it be a financial success, is apt to force a heavy aftercrop of more or less similar schemes. In these cases it too often follows that the modest anxiety and patient forethought which have led to the first triumph are altogether discarded by those who rush to follow in the same path. B. has tunneled under the Thames; therefore C and D will fight for authority to tunnel under the Mersey, and E and F to tunnel under the Channel. Talk of the latter project as wild, and its supporters will point with triumph to the little *adit* by the Tower.

Tunneling, indeed, is not an invention of the present day, nor of the present century. That great engineering people, to the influence of whose institutions we owe so much of the very framework of modern civilization, wrought tunnels which endure to the present day. Two thousand two hundred and sixty-four years ago, the miners of Furius Camillus drove the famous *Emissarium* through a part of Mount Alba, and tapped the swelling waters of the lake of that name. Etruscan science, on this occasion, directed Roman energy. But the *tufa* of Italy, a material which behaves under the pick of the miner in a mode very similar to the English chalk, is bored and drilled with shafts, and *adits*, and lofty tunnels, in all directions. The gallery of Posilippo is familiar to every visitor of Naples. The curious system of galleries and caverns known by the name of the Grotto of the Sibyl, dates from a remote antiquity. Whether it were from an observance of hydraulic laws, from want of a trustworthy material for pipes, or from the conviction that the steady unchecked action caused by gravitation was best suited for the permanence and purity of a water-supply, we need not now pause to inquire. But certainly a knowledge of the engineering works of ancient Italy might have taught the English predecessors of Brunel more than they ever knew about tunneling.

The school for tunneling in England has been, of course, underground. In our mines, especially in our coal mines, the problem of constructing subterranean galleries has long been solved. In certain districts, such, for instance, as that of the Peak, in Derbyshire, vast natural caverns open out in the living rock, glittering, when lighted up by the miner's torch, with sparkling stalactites, accessible, in places, only by narrow and low-roofed passages; and at times traversed, or occupied, by rivers, which long borrow from the light of day. In one Derbyshire cavern a river precipitates itself down an unfathomable abyss, and what becomes of the water is unknown.

But with all our practices as to mining, and all our acquaintance with natural subterranean galleries, the progress of the tunnel engineer was slow in this country, until the exigencies of the line selected by Stephenson for the London and Birmingham Railway led to the simultaneous construction of four wide and lofty tunnels, of dimensions before rarely attempted. It is true that the method of piercing the barrier that divided valley from valley had been pointed out, no less than the main directions of the best line of communication had been indicated, by Telford. The Grand Junction Canal was the pioneer and guide of the London and Birmingham Railway. But the canal tunnels were reduced to the minimum cross section. They admitted a canal boat, with the depth of water requisite to float it, and no more. In the earlier tunnels the boats were propelled—or, we might say, coaxed through—by the barbarous and painful expedient of the boatman's lying on his back and pressing his feet alternately against the roof of the tunnel.

In the case of the Thames and Medway Canal, a tunnel of larger dimensions was cut, through the chalk, at Rochester. A narrow tow-path was formed, in this instance, by the side of the water-way. In that tunnel, of some 2,000 yards long, the chalk in some places gave way, and lofty caverns diversified the usual elliptic section of the arch, which in only a few places, was protected by brickwork. When the Gravesend and Rochester Railway was laid through this tunnel, the Government Inspector, Lieut.-Gen. Sir C. Pasley, satisfied himself of the solidity of the chalk roof by the military expedient of *firing at it from a mortar.* He only used, however, wooden plugs.

The Kilsby tunnel was the scene of a most protracted, and for a long time a precarious, struggle of Robert Stephenson, with the great enemy of the tunnel miner—water.—So long and so continuous was the influx, and so far were the methods at first employed from being adequate to keep it under, that the abandonment of the work was at one time all but resolved upon. A quicksand full of water had been tapped by the tunnel, and till this was emptied, satisfactory progress was impossible. Notwithstanding the increased command of steam and of mechanical power which the last thirty-five years have placed at the command of the engineer, the experienced man will yet even now look grave at the prospect of tunneling through a hill that is likely to be wet, unless he can allow of the tapping of the springs, and the *bleeding* of the internal lake, by gravitation.

In this contest with the water at Kilsby, Robert Stephenson could indeed avail himself to some extent of the experience gained by Sir Mark Brunel and his assistants in their long struggle with the Thames. But the Thames Tunnel was unlike any other work. It was long considered, deservedly, and is still ranked by foreigners, as one of the wonders of the world. Skill, patience, energy, enough to have reared a monument of the loftiest dimensions, were buried in that horrible mine. Engineer after engineer was knocked up by labor, by damp, and by the ill effects of the deposit of the London sewage in the bed of the river. But the Thames Tunnel was a work *per se*,—a marine, or rather river, work, under most unfavorable circumstances, rather than a tunnel proper. The normal idea of the latter work is that of boring through the earth. The material may vary; props, and struts, and polling boards may be more or less constantly required; water may pour in, and necessitate constant pumping; but these are the accidents of the case (and very unpleasant accidents they are). They are not essential or constant obstacles to the boring through of a rocky or chalky barrier. Earth, or rock, is the natural bed of the ordinary tunnel. But Sir Mark drove through shifting mud. The square platform which grew together, brick by brick, as his many-partitioned shield was driven forward, was often within but a few feet of the bed of the Thames. It is even probable that, had the problem been affronted in the first instance, the engineer would rather have preferred to construct a double brick arch, working from one end, through nothing but water, than to deal with the ever-varying difficulties of mud, and silt, and clay, and wholesale inpour of the tide.

Indeed, Mr. Barlow claims for his well-considered and simple shield, the merit that it would be so adjusted as to drive a tube ahead through water. It is far from being impossible that such a procedure should be carried out.

In the case, however, of the actual subway, the chief point to note is, that a wise provision has been exercised in fixing the level of the work so deep in the London clay that not a drop of water has entered the drift-way. That necessary for the purposes of the work has been send down the shaft. In fact, though no engineer would have felt justified in making the experiment, there is little doubt that the simple expedient of mining through the clay at the same level, "polling" the drift-way, and following the miners by a gang of bricklayers, who should have turned a brick and a half ring round the aperture, would have met with uninterrupted success. The one thing necessary in a case where, as in this instance, no faults occurred in the clay, would have been to keep up such a rapid rate of progress that the arch should always have been keyed in before the clay began to "creep." How certain, and how formidable, that creeping action is, Mr. Stephenson had ample proof in the Primrose-hill Tunnel. Under the influence of the successful experience of the Watford Tunnel, driven for the most part through solid chalk, the originally designed invert of the Primrose-hill Tunnel was countermanded. But the clay betook itself to fill up the hole drilled through its bowels; and the invert had to be put in, in very much of a scramble after all.

Men familiar with this description of work looked with a sort of amused surprise at the rose-colored statements which from time to time appear in the public journals as to a "Channel Tunnel." They do not say that such a work is impossible. They do not even care to form a distinct opinion on that head. But they are very well contented with the applicability of the proverb, "*Le jeu ne vaut pas la chandelle.*"

A better communication with France is no doubt both extremely desirable and perfectly feasible. Our present mode of transit, obnoxious as it is to the majority of ourselves, islanders as we are, and still more miserably and terrifically obnoxious (to judge from their countenances on deck) to most of our Continental neighbors, is hardly up to the requirements of the day. A safe, speedy, regular transit, free from doubt, from risk, and, above all, free from the fear of that horrible *mal de mer*, is what the English public have the right to expect of the profession of civil engineers, and what that profession will place at the command of the public, on the one sole necessary condition of being furnished with funds. These funds must be large, for the waves of the Channel are rough and tempestuous. But to speak of the sum requisite as one which would be adequate to the construction of a sub-marine tunnel, 30 miles long and 250 feet (some say yards) below the level of the *Manche*, is, to our mind, nothing better than grave trifling with an important practical subject.

It is curious to see how the non-professional imagination has not only run to flower, but to seed, about this question of crossing the Channel. The most remarkable feature in the case, moreover, is, that hardly any scheme is so absurd as not to find solemn-visaged propounders and open-mouthed admirers. It is evident that the material on which Law counted as the basis of his imaginary wealth is still to be found in rich abundance within our shores. It is only necessary to dig. *Les badauds ne passeront jamais.* Neither railway kings, with their royal mode of making things pleasant, nor colossal contractors, with their lines to develop traffic; nor financial companies, with their periodical crashes; nor Brighton directors, with their eight millions laid out so as to earn an annual loss, exclusive of the perished and annihilated interest; nor Chatham and Dover magnates, with their discounts of all per cent, have had more than a temporarily enlightening influence. We are told of scientific French evidence in favor of a grand Channel tunnel. By way of making a few preliminary inquiries, the Chancellor of the Exchequer is to be asked for the trifling sum of a couple of millions on account. The French Emperor, it is added, looks favorably on the scheme, and has given a conditional promise of as much more. All right; we rejoice to hear it.—We have only one point on which to insist. Let us get the French Emperor's money down *first*. Then it will be time enough to inquire about our own installment.

It is proposed, as caution is always desirable in engineering matters, that a drift-way should just be run under the Channel in the first instance, to prepare the way for the tunnel. The suggestion is at once economical, prudent and practical. Let us suppose a drift-way to be run, some five feet or six feet high and wide. Is it to be timbered, or arched, or lined with iron? As the meeting from the two ends would be a thing forbidden by the calculus of probabilities, it will have to be worked from one extremity. As we get on—say beyond the twentieth mile, how will the miners be sent in to their daily work?—how supplied with air or materials?—how will the excavated chalk be sent back to land?

Galleries in chalk are infested, as miners are well aware, with choke-damp. What would be the quantity of choke-damp that would exude from 280.000 superficial yards of chalk surface (when the drift-way had advanced *only* twenty miles), and how would it be withdrawn?

Water infiltrates through chalk. A very small head of water will cause infiltration for a considerable distance. Where bands of flint occur they act like layers of sponge. All the wells in Strood, within a considerable distance of the Thames and Medway Canal, were rendered salt by infiltration through the chalk, when the brackish water of the Medway was admitted into the canal; and the company had to pay, and did pay, heavy damages in consequence. What would be the infiltration through the gray chalk due to the pressure of the water of the Channel? What would be the difference between the exudation from the 280,000 yards of surface at high tide and at low tide? How would the water, on its most modest estimate of its rate of infiltration (which by the by, would increase *de die in diem*), be removed? A few of these practical questions must be answered before we can undertake to speak, with any idea of serious investigation, as to the prospects of the Channel Tunnel.

But we are not limited to one scheme.—Their name is legion. One amateur proposes the formation of an embankment across the Channel, the top to be some 30 feet *below* low-water mark. Rails are to be laid on this embankment (which is kept down for the benefit of navigation), and long-legged carriages, of novel structure, are to run backwards and forwards over the submarine railway. We should like to let the laying of the permanent way to the projector.

Another gentleman proposes a floating tabular tunnel. It is to be moored at certain distances by chains. The process of anchoring and straining the chains at the bottom of the Channel would be highly interesting. Supposing—not to make two bites of a cherry—the tube complete, moored and at work. What a grand idea to think that the whole service of the Continent, and the lives of all who happened to be at any time in a structure that recalls the legend of Mahomed's coffin, would be at the mercy of a beggarly gun-boat, or a mischievous torpedo!

In fact, we warn our friends, when called on for subscriptions for a Channel bridge, or tunnel, or hybrid between the two, to button up their pockets, and wait. The limits of the service of the engineer are, no doubt, rather financial than physical. The limits of speculative imagination appear to be equally removed from the barriers of prudence and from those of experience.

Returning for a moment to the Tower subway, we would mention that the work has been carried forward by the advance of a tabular wrought-iron shield, about 8 ft. in diameter, which is so constructed as to form a close bulkhead in case of need. As this shield is pushed forward by screws, the excavators opening out the ground for a few feet in advance, the permanent tube of the subway is fitted into place behind it, being cast in 18-inch lengths, each consisting of four segments; three of which are of equal size, and the fourth is a mere key-plate, 14 in. or 15 in. wide. Length by length these narrow plates are bolted on the face of the tube, being protected, until firmly fixed, by the shield. The introduction of the narrow wedge-piece has proved a great facility in fitting together the segments of the tube.

The internal diameter of the completed tube is 7 feet. A narrow railway will be laid throughout, and the passengers, being lowered down the shaft by a vertical hoist, will be carried through the subway in an omnibus specially constructed for the purpose, propelled partly by gravity and partly by haulage by a stationary engine. A curious feature in the actual construction of the tunnel is the filling up of the small space, excavated outside of the tube, with blue lias grout. A hole is left in each plate, and through this the grout is driven by a large syringe until the aperture is completely full. The mixture dries so rapidly that it is unnecessary to plug up the holes on the removal of the nozzle of the squirt. How far that irresistible oxidation of the iron (by absorption from the grout), of which we have recently seen such a striking instance in the tomb of King Henry VII, will proceed, remains to be seen. It seems almost a penny-wise-and-pound-foolish proceeding not to have enameled, galvanized, or otherwise protected, the inaccessible exterior of the tube from a very formidable danger which there is no means of detecting until it is too late. Mechanically considered, the injection of the grout is admirable. Chemically regarded, we fear that the same cannot be said.

We avail ourselves of the opportunity to call the attention of all managers of tunnels, mines, and similar works, to the immense facility afforded to the work by the use of the electric telegraph. A constant and instantaneous communication is kept up by the wires between the engine-driver and the face of the work. Lowering and raising of materials, and admission of air by the fan-blast, are thus precisely directed by the foreman on the work itself. The sense of confidence that would be inspired in any case of danger by the possession of this mode of communication would be beyond all price.

THE MANUFACTURE OF RAILS.

From a paper by Mr. E. Williams, before the Iron and Steel Institute, and the discussion following.

In this paper Mr. Williams stated that he proposed to give as concisely as he could the opinions he entertained as to rails, and to consider, from the stand-point of a rail-maker, the several kinds of rails in use, the merits and demerits of each, together with the processes of manufacture generally used. The paper said: The rails of to-day are of two distinct kinds—those made from ingots and those built up; and it must be admitted that—questions of cost and possible supply not considered—ingot-made rails are best. We are in the habit of describing the two kinds as steel rails and iron rails—a description obviously incorrect—because the Bessemer rails now making have a percentage of carbon much lower than that of steel proper as we used to know it. Besides, it is, so far as I know, impossible to define when iron ends and steel begins. It will then be as well to call the two divisions ingot rails and piled rails.

For many years makers of iron by the old processes have desired and endeavored to produce ingots or blooms, each from a single puddled-ball, that would roll into rails. This, if it could be done, would, I have no doubt, make rails equal to any ever made; but the difficulties seem insuperable. Puddled-balls of sufficient size have been, and may be obtained; but it appears impossible to produce moderate compactness of the iron without more work upon it than is possible in one operation. I have come to the conclusion, though most unwillingly, that we shall not succeed in producing by puddling, workable, unwelded, solid blooms and, so far as our present knowledge extends, ingots cheap enough to make rails on a considerable scale are only to be obtained by the Bessemer process. Whether or not the Siemens-Martin process can compete, in point of cheapness of production, with the Bessemer process, is as yet unproved, and the question need not arise here. It is sufficient now to know that both can, without doubt, produce ingots that roll into rails without much difficulty, and that such rails, being free from the possibility of lamination, must be more enduring than built-up or piled rails, however carefully made. It is not unlikely that further experience may determine the precise constitution ingots should have to produce the most enduring rails, but at present this is matter of opinion only. The freedom from welds and layers is an enormous advantage, and the use of ingot rails will, I feel sure, go on increasing, though the rate at which they will push piled rails out of existence must, of course, depend on the relative costs.

If the phosphorus difficulty could be got over, and the cheap pigs of the Cleveland district were available for the Bessemer process, there would be so great a reduction of cost that ingot rails would be almost as cheap as piled ones, and the latter must at once give way; but there is not at present any good ground for expecting that such a change is near, and I see no reason to suppose that for some time to come ingot rails will become anything like universally used, because of their price. The removal, in February next, of the bulk of the present Bessemer royalty-charge, will, no doubt, reduce the selling prices of ingot rails; but I am mistaken if, after all, they can be produced so as to be sold within 40s. or 50s. per ton of the average selling price of good piled rails, the life of which, in the ordinary portions of a heavily-worked railway, would be about fifteen years. For the very severely-worked places ingot rails, at almost any moderate extra price, are, of course, best.

Strenuous efforts have been made by nearly all the great iron makers everywhere to produce steel topped rails, which, it was hoped, would be much more lasting than the usual piled iron rails, and less costly than ingot rails. Puddled steel seemed to offer a cheap and good material for this, and after some difficulty to begin with, it was produced of uniform quality. It is, no doubt, a material capable of resisting well the wear and tear of railway stock, but it could scarcely be welded at all, and as it could not be obtained in solid blooms of the rail size, the system failed and has been abandoned, in this country at least, entirely. That Bessemer steel slabs can by great care and skill be so fastened to iron as to make rails that will wear well is proved by the instances of the rails supplied to the Edinburgh and Glasgow Railway and to the Swedish Government. Probably there have been some other instances also, but I do not expect to find such rails coming into general use, because of the difficulty of welding on the steel plate, which is not much, if at all, less than that of the puddled steel before spoken of. It need not be told to this meeting that steel, however mild, will only stand a comparatively low heat, while iron, to weld at all, must have a high one. Giving the steel top a mechanical grip is, no doubt, to make the best job possible, but the channel steel slab has the disadvantage that the horns prevent the escape sideways of the superfluous cinder, which at best interposes too much between the layers to be welded together. This could not fail to produce faulty welding, which the traffic of an English railway, such as the North-Eastern, would certainly bring to light despite the mechanical fastening.

So far as I can see, then, the only choice as to rails lies between those made from ingots and piled ones, and in the uncertainty as to the Siemens-Martin process it may be assumed that the Bessemer process will supply the former. I do not desire to convey any doubt or even opinion as to the practical value of the Siemens-Martin process ; but it is not yet, in England at least, in operation for rail making on more than an experimental scale, and it is therefore uncertain what proportion of the rail ingots of the future it will supply. The present price of ingot rails is about £10 per ton for usual flange sections, and it is, I believe, the fact that this is not remunerative. After February next makers will save most of the royalty for patent right, and it may be assumed that rails will go down say to £9 per ton. While ingot rails are at anything like this price, good piled rails, the average selling price of which is not £6 10s. per ton, and which, under moderate traffic would live on the average 15 years or more, will, I believe, hold their ground and be in demand. I wish to make it clear that my remarks apply only to good iron rails; the very lowest kind is only bought by those who give themselves no concern as to quality, and first cost will in such cases be the only considerations.

It is not unfrequently asserted that, as a rule, the rails (of course all piled rails) of twenty years or so ago were of a more enduring kind than those supplied now, and I think there is some truth in the accusation. It must not, however, be forgotten that the duty imposed on rails now is very much in excess of that they had to bear in the early days of railways ; and that, therefore, mere length of life is not a correct standard by which to measure their quality. As the weight upon the rail increased, engineers and manufacturers simultaneously adopted the use of more fibrous iron as a preventive. Still every now and then a rail would break despite the extra endeavor to prevent it, and notwithstanding the heavy and heavier tests which rails were required to stand. This has gone on for many years until not a few of the specifications framed by engineers, certainly with the view of ensuring excellence of quality, bring about the reverse, because to meet them, rails are made of fibrous, and therefore difficult welding iron, at an increased cost, and less serviceable than those made after a simpler system. Even, after all the additional cost and the diminished value of the tougher rails, there is an occasional breakage (as there is also now and then a breakage of ingot rails), and I am of opinion that it will be so, despite all possible care, and irrespective of price.

We all know that a percentage of piles or ingots heated are, even by the best workmen, so over-heated, at some stage or other, that they fall into pieces, or become torn in the rolls; there are also, no doubt, some which are heated a shade short of this point, and just hold together, but are almost as brittle as porcelain when finished. This occurs while the great bulk of the rails are abundantly strong, and I do not see how any system of testing can detect the unfortunate instances. They cannot under any tolerable supervision be more than a small proportion—under good watching very small—but I am afraid they will always be a proportion, as there is in the case of crucible steel tyres, which cost eight or ten times as much as rails, and which have all possible care and skill devoted to them. Supposing the all but broken rails to be 1 in 100,000, it will be evident that there is small chance of that one being selected for testing, and if it were chosen, it would be found so exceptional that nothing more serious would follow than the testing of a few more rails to prove that it was exceptional.

I do not at all advocate the discontinuance of the system of testing rails—no prudent maker would abolish it even though it were not insisted on, but it is, I am sure, the fact that the excessively heavy falling weights, prescribed frequently, do necessitate the use of iron for rails that welds with difficulty, and, therefore, does not make the best rail for wear. To meet the severe falling tests it is absolutely necessary to use fibrous iron, and not to heat too much—in fact, to make the piles of iron that, do what you will, is very difficult to weld, and then not to give them the amount of heat necessary to make as good a weld as might be. On this subject I have thought and experimented much, during a somewhat long experience, and I am satisfied that a fibrous nature and weldability do not go together, and that only well-puddled, crystalline iron welds easily, and, therefore, with moderate certainty. Given any kind of wrought iron, it welds more easily in its first stage, that of puddled bar, than at any future one; and the effect of roughing it down, that is, of extra piling and rolling, is always to diminish the weldability of the resulting rail piles. Those who make cable bolts, best boiler plates, and other similar iron, know how certainly they are spoiled if they are worked hot—in other words, if they are welding hot. Cable bolts for a chain are not the worse, but the tougher and softer, because the layers of which they are composed are only firmly struck together, and not welded; but in rails welding is the very life itself. As often as opportunity offered, I have carefully examined rails that had borne an unusual amount of work before becoming so worn as to be replaced, and in, I think, every instance they were what we now would call very brittle rails, and had a rough crystalline fracture when broken under a falling weight.

It is, I think, undesirable to use rail piles of great cross sectional area, which are less likely to be heated equally to the centre than were the small piles of a century ago. Rails at present are heavier and longer than formerly, and it would not, I presume, do to go back to piles 6 in. square, or thereabouts; it would, however, I think, be well not to exceed 8 in. by 8 in., which, with blooming and double-heating, might be well welded. The two great rail-producing districts of this country are Wales and the North of England, and each has a system of working different from the other.

These systems have been explained in detail, and with the aid of diagrams, Mr. Williams went on to say "that the Welsh system has the merit of more work on the iron, that is, greater consolidation, than is obtained by the north of England system. This is a doubtful advantage, if it is really, as I believe, that the iron for rails is, as a rule, too much worked, while it has the demerit of having many through welds in the heads of the rails. The north of England system produces hard crystalline heads, with the fewest possible welds, and when the iron of this district is not too much worked, and thus made fibrous, it is of the most weldable kind, though somewhat brittle. Such iron, it seems to me, is likely to produce enduring rails, and I firmly believe that with proper attention, piled rails can, and will, for a long time yet, be made from it, so enduring as to compete successfully with good ingot rails, produced by the Bessemer process." Mr. Williams concluded: "My desire has been to lay before those who make, and those who use rails, the conclusions my experience has produced, as to the causes of the unsatisfactory wearing power of piled rails, and to show how, in my opinion the evil may be abated. The subject is very important to all, and to no class of men more than to those who, like myself, make piled rails. These are now in competition with ingot rails of the Bessemer process, and cannot, I think, possibly continue in demand, unless the greatest care be given to the manufacture, both as regards the iron used and the welding. Welding, I hold to be the one thing needful, and we should never lose sight of it. As I have before said, the chance of obtaining thorough welding would be much increased by not insisting on more toughness and fibre than is absolutely necessary to guard against so much brittleness as would bring about breakages o the rails in work."

Mr. J. T. Smith (Barrow-in-Furness thought there was a point on which Mr. Williams was misinformed, and that was that in a few months (in February) when the Bessemer royalty would be reduced, rails of that character could be had at £9 per ton. So far as he had been able to ascertain, rails had been at very nearly that price for a considerable time, and the majority of the steel rail masters were looking forward to the time when the royalty would be reduced, that they might be able to recoup themselves for the expenditure they had had on their works.

Mr. Walter Williams (Tipton) briefly described the manner in which rails were manufactured on the Continent, especially in Russia. He had seen from a 12 in. pile rail finished at one heat, the head crystalline and the flange fibrous. If they were able with their common puddled iron to make rails that stood the test that our iron stood, there must be really something in the first process. The rails were rolled out at the rate of one a minute—100 revolutions were attained by the rolls—with perfect crystalline top and fibrous bottom. The welding must be perfect, or the defect would evince itself in the crystalline top. The iron was similar in quality and character, and if they were able to do it there, it must be possible to do it here.

Mr. Hopkins (Middlesbrough), as one practically connected with the manufacture of rails, presumed the author, in condemning the system of excessive testing, applied his remarks especially to double-headed rails. If so, he entirely agreed with him. Practically, a lighter test was sufficient to secure a thoroughly good, general wearing rail, and a rail that would stand the traffic of any railway. As regarded the rail with wearing head and flange foot, to make a bearing on the sleeper, a much heavier test could be applied than in the case of double-headed rails; for in the former the fibres were at the foot of the flange of the rail, a crystalline head being still preserved.

Sir William Armstrong need hardly say that, in the manufacture of guns upon the coil system, a perfect welding was of just as much importance as it was in the manufacture of rails; and great attention had been given both at Elswick and at Woolwich, to the devising of a test which should indicate with some degree of certainty the fitness of the iron for the purpose of making a perfect weld. The conclusion arrived at eventually was this (and it was arrived at both in their practice at Elswick and at Woolwich), that in proportion as the iron had a steely character, so in proportion it was unfavorable for welding. The indication of its steely character was obtained in this way—they took a specimen of the iron, heated it to a certain point, and then plunged it into water; if they then found its tensible strength was increased beyond a certain limit, it was rejected as unfavorable for welding. That iron welded most perfectly which underwent no increase of strength in the process of hardening. Almost all iron did receive an accession of strength similar to that observed in steel by the process of plunging when hot into cold water, though to a less degree. He had a little difficulty in reconciling what he had just stated with what Mr. Williams had said in reference to the constant reworking of the iron, unless it did assume something of a steely character, which he had some difficulty in understanding. Then there was another point on which he might speak, though with more diffidence, and that was in regard to the mode of testing rails. The test which was ordinarily practiced of selecting a particular rail—allowing a heavy weight to fall upon it—might be very well for indicating the general character of the material, but it was not at all a proper method of welding out the rails which were defective in manufacture. He did not see why there should be any difficulty in exposing a rail to a moderate test of that kind. It would not be difficult to devise some apparatus by which that should be done without any manual labor at all. If the rails were laid on a moving machine and struck with a certain force which would not endanger a good rail, but which would as certainly break all rails which were inherently bad, the end would be answered.

Mr. I. L. Bell felt that the quality of rails generally had suffered materially from the wish on the part of the buyer to obtain the rail at far below the cost at which it could be produced, and secondly, harm had been inflicted on the manufacturer by the demand for a species of test utterly unnecessary and excessive. They had on the North-Eastern Railway a great number of rails which had worn uniformly down until from absolute wear they had become unserviceable. It became a most interesting question to him to know what was the character of that iron which had been better able to stand the wear and tear of the railway than iron which appeared to be of a much better quality. He subjected it to an analysis, conducted by Mr. Marreco, a very competent person, who discovered not in one instance only, but in many, that the rails were distinguished by the excessive amount of phosphorus they contained; and, in point of fact, was precisely due to that quality, in which, probably, Cleveland stood preminent.

Mr. T. W. Plum (Old Park Ironworks, Shropshire), thought it worth investigation whether a homogeneous rail from the solid bloom might not be made very nearly approaching in durability and quality to some of the steel rails. The days of steel rails were coming very fast upon them, and it might be worth while for the iron rail makers to turn their attention to the subject. As regarded welding he might say that he had had some little experience in working iron for guns at Woolwich, and some time after that he had to start a tyre mill on the coil principle, similar to that adopted in the construction of guns, except that the bars for the welding were flat instead of square as used for guns. He encountered some difficulty in getting the coils to weld properly, and after some little experience he had them made with convex sides; and so superior was the result obtained by the use of convex bars that, having on some occasions had Swedish iron which was difficult to weld made into tyres, the result was perfectly satisfactory. It was desirable to consider whether rails could not be made from solid blooms, instead of piles as hitherto.

SCIENTIFIC *vs.* PRACTICAL SCHOOLS.

From the "New York Times."

Although the subject of education—classical and scientific, practical and polite, popular and technical—has never been more warmly and widely discussed that at present, there are notable differences of opinion and practice regarding the educational requirements of classes, and the most effective methods of instruction. While we rejoice at the maintenance of the classical department in the great free school of this city; while we cannot too highly appreciate, in this greedy and utilitarian age, the polite and scholarly culture of our older universities, it must be admitted that the dissemination of *practical science* is the great problem of the day.

Education is popularly divided into "classical," that is to say, scholastic and polite, and "scientific," by which is meant practical, useful, and adapted to the daily and modern wants of the nineteenth century workers: but it should appear that this classification is incomplete. If we mean by "classic," pure, chaste, refined, then some of the natural sciences, and above all, the higher mathematics, exhaust that definition, though usually classed as scientific; and certainly nothing could be less practical or more imaginative, not to say poetic, than for instance, the mechanical engineering taught in many of our scientific schools.

In as far as education is a disciplinary process for fitting the mind to work, there must be little to choose between Greek and mathematical roots; but in as far as it pretends to unfold the particular and practical arts and sciences by which graduates can earn fame and bread, it must be admitted that the curriculum of our practical schools, especially in mechanical science, is singularly defective. In his address before the mechanical science section of the British Association, Mr. Siemens, the President, gave authoritative expression to this idea by saying that the information conveyed to students by professors lacking themselves practical experience, "tends to engender a dogmatical conceit, which is likely to stand in the way of originality in the adaptation of new means to new ends; on this account I should prefer to see a sound 'fundamental' education, with a sketch only of the technical arts, followed up by professional training, such as can be only obtained in the workshop, the office or the field." Those who are familiar with the real requirements of practical scholarship, will recognize this to be a peculiarly timely and wholesome statement of the case—but it is a pretty severe commentary on our technical schools.

We wish to be particularly understood as not applying these strictures to all branches of scientific culture. The pure mathematics, as made signally practical in navigation and in certain features of construction, are wholly theoretical, and the authority and method of their teaching in our better schools are unexceptionable. So it is with chemistry, in most of its ramifications, although practical metallurgists could wish for more definite instruction, and less general speculation.

The successful teaching of mechanical engineering, however, must be founded upon an intimate knowledge of the practice. In some branches of technical instruction, lectures are well enough illustrated and improved by means of visiting, from time to time, the establishments where the science is reduced to an art. But neither the theorist, nor the careful observer, nor even the amateur mechanic, can teach young men to run a machine-shop, or to build, or even design steam engines, rolling mills and general machinery, for the following reasons:

First—Although the strength of materials, as subjected to different kinds of statical strains, is a matter of text-book information, machinery designed by these lights *alone* always fails. There must be, above and beyond all tables and formulæ, a certain mechanical judgment as to the proportions and relations of parts. A bearing that will carry a certain load in a stationary engine, housed, clean and never overstrained, may be very inadequate to the same nominal service in a rolling mill or in a locomotive, where frictions and strains may be excessive. The circumstances of over stress, exposure, attendance, convenience of repairs, and other accidental conditions may entirely change the designs of machines subjected to nominally the same service. Experience in construction has also established certain principles of departure from general laws of strength. The reduction of friction, and even more notably, the steadiness and balance of parts, requires in many positions an excessive amount of material. On the other hand, especially in the case of the machinery of transportation, experience has shown the importance of reducing weight at the cost of stronger materials and shapes.

Secondly—The principles of economy, not only of material, but of the work put upon it in construction and in maintenance, must be perfectly familiar to the successful mechanical engineer. No matter how well a machine will perform its functions, if the shape of the parts is such that they cannot be cast, or wrought, or finished by the tools at hand, with the least amount of handling or work, or if the parts are so put together that they cannot be easily taken to pieces for repairs, the machine is to that extent defective.

It is, therefore, evident that mechanical engineering cannot be successfully taught by professors whose knowledge of machine shops and foundries has been derived from walking through them with their classes. Nor does it follow, on the other hand, that one must serve an apprenticeship at the vise and the lathe to acquire the principles of mechanical construction. There is, indeed, little or no strictly educational literature in these branches, but of course there will be, and it will be adequate and suitable, as soon as the men, who alone can produce it, are called upon for lectures and text-books. Until then—until instructors are not only scholars, but the personal designers and builders of successful machinery, students in mechanical engineering had better take Mr. Siemens' advice, and simply master the elementary principles of physics, dynamics and mathematics, and then go to work in drawing rooms, foundries and machine shops, even under the embarrassment of but partially utilizing the many hours at the vise and the lathe, which could be more profitably and economically devoted, if one had more practical teachers in our "practical" schools. Let no one be deceived by names, or by proposed courses of study. The steam engine, for instance, is the subject of lectures in some of our colleges, that brings the invention nearly down to the time of Watt. The training of professors in mechanics and engineering that has been commercially productive, as a business, is the test by which the usefulness of their schools may be chiefly determined.

When young men who want to excel in this branch of industry, hear that experts like Fairbairn, Corliss, Whitworth, Sellers, Worthington, Armstrong, Ramsbottom, Allen, and many other of whom these are types, are going to lecture on steam and general machinery, let them go and listen, at any cost. It may be difficult, but it should not be impossible to secure this kind of talent and training for our chairs of mechanical engineering. Few public questions are of more importance than the proper instruction, in this distinctively engineering age, of the young men who are crowding into this profession. The managers of our educational institutions are charged with a grave responsibility, and the various men of means who are contemplating the endowment of schools, can hardly extend their liberality in a more useful and timely direction.

CABLE TOWING on the river Meuse, which we have heretofore described, appears to be an entire success. All the embarrassments of swift current, varying depth, locks and sharp curves, appear to have been overcome. Inasmuch as it would not interfere with horse-towing, nor require any change in the works, and since a State expenditure of only some $500 per mile for cable would be required, we hope that, say, 50 miles will be at once laid on the Erie canal.

THE "DUTY" OF INJECTORS.

From "Engineering."

The question as to the relative economy of injectors and pumps as boiler-feeders has been frequently discussed, but, as a rule, the arguments on both sides have been founded upon data greatly wanting in scientific accuracy. As far as we are aware, scarcely any reliable experiments have been conducted in this country to ascertain the amount of steam actually used by an injector in performing a given amount of work; and we are, therefore, glad to see that, in an appendix to a recent number of his work on "Steam, Air, and Gas Engines," Mr. John Bourne gives the details of a series of experiments lately carried out by him to obtain some definite information on this point. Mr. Bourne's experiments were made with a No. 6 Giffard's injector, which was made to draw water from a tank, and deliver it, past a loaded valve, into another tank standing at a lower level. The valve, which was of the piston kind, was loaded by a spring-balance, so that the pressure upon it could be adjusted, and both tanks were fitted with gauges. Steam was supplied to the injector from a small vertical boiler, the chimney of which was furnished with a damper, so that an uniform pressure of steam could be maintained, while the boiler was also fitted with a graduated gauge, so that the quantity of water evaporated during each experiment could be noted. The temperature of the water supplied to, and delivered by, the injector was also ascertained at numerous frequent intervals.

Mr. Bourne, however, although he gives the full details of his experiments—which are altogether 67 in number—does not show how the heat abstracted from the boiler is utilized, but he merely remarks that: "As, then, these experiments show the quantity of water evaporated from the boiler, under a determinate pressure, and also the quantity of water lifted against a determinate pressure or head, by the volume of steam answering to the quantity of water evaporated, the duty of the instrument, in any experiment, can easily be deduced, *and it will be found to be very low.*" As to this latter deduction, which we have printed in italics, we either agree or disagree with Mr. Bourne, according to the meaning assigned to the term "duty." If the "duty" of an injector is measured merely by the quantity of water delivered by it against a given pressure by the consumption of a given quantity of steam, then undoubtedly the "duty" of the instrument is, as Mr. Bourne states, extremely low. But an injector not only serves the purpose of a pump, but also heats the water delivered by it; and when employed as a boiler-feeder, the only heat which can be fairly said to be absorbed in working the instrument is the difference between that abstracted from the steam passed through it and that imparted to the feed-water. Measured according to this standard, the "duty" of an injector will be found to be very high; indeed, so high that it would require some experiments of a far more precise character than any yet conducted with the instrument to determine the absolute loss. It is, we think, far from being generally recognized how small a proportion of the steam passed through an injector is actually utilized in forcing the water into the boiler; and it may be interesting if we analyze one of Mr. Bourne's experiments, and show the information which they afford on this point.

As our example, we shall take an experiment in which the pressure against which the water was delivered was the same as that at which the steam was supplied, the circumstances being thus those under which the majority of injectors in use work. The details of the experiment are as follows:

Duration of experiment	12 minutes.
Pressure in boiler	30 lbs. per sq. in.
" against which water was delivered	30 " "
Quantity of water evaporated..	5 gallons.
" " drawn from supply tank	90 gallons.
Quantity of water delivered as measured in receiving tank..	100 gallons.
Initial temperature of water ..	52° Fahr.
Mean final temperature of water	117° Fahr.

As the water in the boiler would have a temperature due to that of steam at 30 lbs. pressure, namely, 274.4°; and as water at this temperature weighs 58.17 lbs. per cubic foot, the 5 gallons evaporated would weigh $5 \times .16 \times 58.17 = 46.536$, or, say, 46.5 lbs. Again, the total heat of steam at 30 lbs. pressure is 1,197.6°, and as during the experiment we are considering the steam was condensed into water at a temperature of 117°, each pound of it lost 1,197.6—117 = 1,080.6, or, say, 1,081 units of heat. The total heat abstracted from the steam used during the experiment was thus $1{,}081 \times 46.5 = 50{,}266.5$ units.

On the other hand, the weight of water

at a temperature of 52°, being 62.377 lbs. per cubic foot. The 90 gallons supplied to the injector would weigh 898 lbs., which, added to the 46.5 lbs. resulting from the condensation of the steam, gives 944.5 lbs. as the weight of the water delivered. Mr. Bourne, however, gives the quantity delivered as 100 gallons at a temperature of 117°, and taking the weight of water at that temperature as 61.7 lbs. per cubic foot, this would correspond to a weight of 987 lbs., or $42\frac{1}{2}$ lbs. more than as determined above. This difference is, however, not greater than might be naturally expected in experiments of this kind, in which, unless many minute precautions are taken, there is a considerable liability to small errors arising from the expansion or contraction of the measuring tanks, etc. If, in the present instance, we take the larger quantity, or 100 gallons, as that actually delivered by the injector, we shall have 16 c. ft. of water delivered against a pressure of 30 lbs. per sq. in., or 4,320 lbs. per sq. ft., this corresponding to the performance of $4{,}320 \times 16 = 69{,}120$ foot-pounds of work. Dividing this number by 772 (Joule's equivalent), we get $\frac{69{,}120}{772} = 89.5$ as the number of units of heat actually required to perform this work. But it has been shown that the steam abstracted from the boiler parted with 50,266.5 units of heat, and there therefore remains 50.177 units of heat to be yet accounted for. But it is stated that the 898 lbs. of water supplied to the injector were heated from 52° to 117°, and this would, therefore, correspond to the absorption of $898 \times 65 = 58{,}370$ units of heat, or more than sufficient to account for all the heat lost by the steam. We, of course, do not for a moment suppose that any heat was created in the injector, and the fact that the amount of heat stated to be imparted to the feed-water exceeds by a small amount that lost by the steam, can only be due to some errors of observation.

Some of Mr. Bourne's experiments were conducted with the injector delivering against both higher and lower pressures than that at which the steam was supplied; indeed, in one instance the injector, when furnished with steam at 20 lbs. pressure, was made to deliver against a pressure of 100 lbs. In this case, however, the quantity of water which escaped at the overflow was equal to 80 per cent of that actually delivered by the instrument. It will be unnecessary that we should repeat the detailed calculation which we have made concerning these various experiments, but we may give, for the purpose of comparison, the results obtained in two instances in which the pressure against which the water was delivered were respectively much lower and much higher than that at which steam was supplied. These details are as follows:

	A.	B.
Duration of experiment....	9 min.	16 min.
Pressure in boiler	40 lbs.	30 lbs.
Pressure against which water was delivered...........	10 lbs.	90 lbs.
Quantity of water evaporated	6 gals.	6 gals.
Quantity of water drawn from supply tank	94 gals.	96 gals.
Quantity of water delivered into reservoir tank	100 gals.	100 gals.
Quantity of water escaped at waste pipe	..	6 gals.
Initial temperature of water,	60° Fahr.	52° Fahr.
Final temperature of water,	116° "	114° "
Units of heat abstracted from steam.............	60,245	60,320
Units of heat imparted to feed-water	52,175	57,766
Units of heat due to work done	29.8	268.5
Units of heat not accounted for above...............	8,040.2	2,285.5

In the case of experiment B, the 2,285.5 units of heat, entered as "not accounted for," were probably carried off by the water which escaped by the overflow pipe. It is worthy of remark, that in the two experiments, of which we give the particulars above, the same volume of water was evaporated and the same quantity delivered, notwithstanding that the circumstances were so different in the two cases. Inasmuch, however, as the temperature of 40 lbs. steam is 287°, and that of 30 lbs. steam 274.4°, the six gallons of water evaporated would, in experiment A, weigh 55.56 lbs., and, in experiment B, weigh 55.84 lbs. It is also probable that if the measuring arrangements had been sufficiently delicate, some other minute differences in the quantities would have been observed.

In conclusion, we think that Mr. Bourne's experiments fully corroborate the opinion which we have on many occasions expressed in this journal, that the injector, while forming an excellent and economical boiler-feeder, is not by any means adapted for raising water or for supplying water under pressure, except in those cases in which the heat imparted to the water delivered can be turned to useful account. While, however, we consider that Mr. Bourne's experiments are of much practical interest, we cannot but regret that a supplementary series was not carried out with a donkey pump of good arrangement, substituted for the injector, the exhaust steam being utilized in heating the feed-water. Some useful comparative results might have been thus obtained, though we doubt whether the measuring arrangements were sufficiently delicate to enable the comparative efficiency of an injector or donkey pump for feeding boilers to be ascertained with accuracy. A thoroughly reliable series of experiments to determine this point is really required, and we trust that some day it will be undertaken. In the meantime our own predilections are in favor of the injector, always supposing that the use of that instrument does not necessitate the employment of cold feed-water where hot feed-water would otherwise be available.

WOODEN RAILWAYS.—During the late war in America the Confederates, in constructing temporary railways and renewing lines which had been destroyed, were compelled on many occasions to use wooden rails as the only kind procurable, and over these rails they transported altogether thousands of tons of baggage, etc., at what, all things considered, were very fair rates of speed. Wooden railways in fact, when properly maue and worked, are by no means bad things in their way, and in countries where timber suitable for their construction is abundant, they may often serve a good purpose by opening up a traffic which as it increases will warrant the establishment of an orthodox iron road. It was a recognition of these facts which some nine or ten years ago led Mr. J. B. Hurlbert, an American engineer, to construct a wooden railway about six miles in length for light traffic, and the results obtained with this line proved so far satisfactory that early last year a line, 47½ miles in length, was constructed to connect Carthage, N. Y., with Harrisville. More recently, also, Mr. Hurlbert has built a line in Canada extending from the Clifton Iron Mines to the Otwegatchie Railway, a distance of twenty-two miles, and it is of this line that we more especially intend to speak here.

The rails of the Clifton Wooden Railway, like those of the Harrisville line already mentioned, are of maple, and are 14 ft. long, by 4 in. wide, by 6 in. deep. They should be laid "heart side" down. The sleepers, or "ties" as they are called in the States, are notched for a depth of 4 in. to receive the rails, and the latter are secured in the notches by wedges of maple plank 4 in. wide and 12 in. long. The switches are made in the usual way. The gradients on the line are in some places as steep as 1 in 15, and the sharpest curves are of but 250 ft. radius, these curves, however, being somewhat exceptional. The engines which have, until lately, been used on the line weigh 10 tons without wood or water, and their load averages from 30 to 40 tons. More recently heavier engines weighing 20 tons have been placed on the line, and it is expected that when the latter has been strengthened these engines will take loads of 60 or 80 tons over the railway from the mines to Ogdensburg, there being for this distance a general fall in the direction of the traffic, although the latter has to ascend in some places gradients varying from 1 in 68 to less than 1 in 60. It is stated, moreover, that on these wooden roads a 14-ton engine can draw easily 20 tons of freight up an occasional gradient of 1 in 21; and the experience of last winter has shown that ice and snow are no worse on a wooden railway than an iron one, the use of a snow plough and sand having enabled the Clifton line to be worked regularly in the winter season, even when the ground was covered with three or four feet of snow. The wheels of the rolling stock used on the line have rims similar to ordinary railway wheels, but a little wider, and the flanges are slightly beveled, so that they may bear against the rails without cutting them.) The trains are run at from 8 to 12 miles per hour, and these speeds can be maintained with safety; indeed, it is stated that no truck has been off the line since the Clifton Railroad was opened for traffic.

The quantity of maple used per mile for rails is about 22,000 c. ft., and it is stated that the cost for labor of placing these rails in position is from $80 to $100 States currency. Besides this, there is the cost of the "ties," and wedges, etc., and altogether it is stated that the complete cost of making and laying a wooden railway of a somewhat superior class to that of which we have been speaking, including a moderate allowance of rolling stock, sufficient for the traffic of the first few years, will not exceed $5,000 per mile. In many instances, in fact, such a line as the Clifton Railway can be constructed, exclusive of rolling stock and large bridges, for $1,000 or £200 per mile. As regards the cost of maintenance, that, of course, depends mainly upon the amount of traffic; but in the case of the Clifton Railway, Mr. Hurlbert states that two men will suffice to keep in order three miles of line, replacing all worn rails that may be necessary. Altogether, we think that sufficient evidence has been afforded by the working of Mr. Hurlbert's wooden railways to show that such lines may be profitably constructed in many cases where, from the nature of the country, the formation of a regular railway would be scarcely warranted. It must be remembered, also, that a considerable portion of the labor involved in the building of a wooden railway could be turned to useful account whenever, from an increase in the amount of traffic, its replacement by an iron road became desirable, while the rolling stock, even if specially built for the wooden road, would also be available on the iron one.—*Engineering.*

AËRO-STEAM ENGINES.

From a paper read before the British Association by RICHARD EATON, Esq.

It is now pretty generally allowed that power and heat are convertible terms, and we have it upon the highest scientific authority that a unit of heat is equivalent to 772 foot-pounds. We are further informed that one grain of coal produces, by combustion, sufficient heat to raise the temperature of one pound weight of water through 1.634° Fahr. Taking the mechanical equivalent of heat at 772 lbs. per unit, as above stated, it follows therefore that the combustion of one grain of coal = 1,261.45 foot-pounds.

Now, with the best pumping engines, either on the "Cornish" or "Woolf" system, the average duty is equivalent to about 94,000,000 foot-pounds, with a combustion of 94 lbs. (1 bushel) of Welch coal; in other words, 143 lbs. per 1 grain of coal as compared with 1,261.45 lbs., whence it appears that the steam engine, in its most improved state, is not able to develop much more than one-tenth into *useful* power of the *mechanical* power due to the combustion of coal. As a rule, we may assume that the more distant the extremes of temperature in a thermodynamic engine, the larger will be the proportion of heat turned into power.

In the steam engine the extremes of temperature, or the difference in the temperature of the boiler and condenser, is *not* very great, and air engines, therefore, in which greater extremes may be employed, offer certain advantages in the production of power. But in their arrangement, construction, and practical working, many difficulties occur.

The difficulties in question arise, 1st, from the destructive action of the heating furnace upon the generator, which, when unprotected by water, is sooner or later burnt out or destroyed. 2d. When high temperatures of air are employed, the wear and tear of working parts becomes very great, and the difficulty of proper lubrication almost insuperable. On the other hand, if *low* temperatures be employed the engine develops but little power in proportion to its size, and the consumption of fuel becomes quite as large if it does not exceed that of ordinary steam engines.

In the consideration of the subject before us a useful lesson may be learnt from the avocations of domestic life. Let the tea-kettle be our monitor. The careful housewife places it duly cleaned and charged upon the fire, and no matter how sharp and clear may be the draught, nor how vivid and intense the gaseous flame, no harm ensues. Let her, however, neglect to keep it replenished, and what occurs—the bottom is destroyed. The water acts as a shield or safeguard to the metal exposed to the vivid incandescence, and in the present state of our knowledge as to the structure of metals, or their behavior when exposed to sharp heat, it is difficult to devise a better protection.

The difficulty above mentioned has hitherto proved insuperable notwithstanding the best efforts of those apostles and pioneers of the air engine—Stirling Ericsson and others. All the ingenuity expended upon the designing and construction of regenerators for utilizing to the utmost the heat of the escaping air, proved unfortunately of no avail so long as the generator, which was the mainspring of the whole, to say nothing of the working cylinder itself, remained liable to premature destruction.

Mr. George Warsop, of Nottingham, as the son of an air-gun maker there, was born with aerial ideas, which, although his only education was received at a Sunday School, and he was sent to work at ten years of age, he turned that education to such good account that before he was twenty he had in leisure moments secretly constructed an air engine. Later in life it was his privilege, whilst a working mechanic in New York, during his engagement with Mr. Ericsson, to observe the weak points in the system of that highly gifted and persevering inventor, and after years of research to supply the deficiencies by a marvelously simple system of mechanism, which, as far as present experience goes, promises complete success by means which, happily for the cause of economy and progress, are compatible alike with physical science and mechanical construction.

It is proposed, firstly, to describe these means; secondly, to enumerate the carefully ascertained comparative results which have followed their application; lastly, to show that these results are in accordance with sound theory.

In the first attempts at practically carrying out the system, the arrangement adopted was an ordinary high-pressure engine, with vertical boiler, as used in the midland counties, where fuel is cheap. An air-pump is added, which is put in operation by the action of the steam engine.

Thus, cold air is taken in by the air-pump, and is forced on in its compressed state through an air-pipe, which, in the case before us, is connected first within the exhaust, then in a coiled form down the funnel of the boiler, then past the fire, and finally past a self-acting clack valve at the bottom of the boiler into the boiling water itself, rising naturally through the water, the air is intercepted and subdivided by diaphragms of metal gauge. Thus a twofold service is rendered by the contact of the elements, the water becoming acrified and deprived of its cohesion and prompted to a free ebullition, whilst the air on rising above the water is saturated by the steam, and the two together pass on to their duty in the cylinder, where saturation assists lubrication. The agitation of the water prevents scaling.

The machine thus constructed, but having two air-pumps, and with cam motions applied to the valves as also to the poppet valves of the working cylinder, gave the following results, results which it must be admitted were sufficiently discouraging to have deterred the inventor and his associates from proceeding further in the matter, but for their faith in the intrinsic soundness of the system, and perseverance in carrying it to a practical issue. The work had to be done under disadvantages of various kinds, on inconvenient premises, which centuries back were a farmhouse standing within the ancient walls of Nottingham, and until the protection of the patent laws had been obtained, the original apparatus was carefully guarded in an unsuspected attic.

The results I proceed to detail:

TABLE NO. I.

Combined Air and Steam Engine.

Coals consumed during experiment.	Weight on brake.	Duration of experiment.	Number of revolutions of brake.	Number of revolutions of brake per minute.	Gross H.P. of useful work done.	Gallons of water evaporated during experiment.
lbs. 110	lbs. 75	min. 140	4,623	33	182	84
Steam Engine only.						
lbs. 110	lbs. 75	min. 115	5,182	45	204.1	66

It is needful to state that the amount of air passed in the boiler in a state of compression was considerable, being as much as 43 per cent of the effective cubic contents of the working cylinder, or consumption of combined fluid from the boiler. And it appeared pretty certain that the power obtained by the increase of volume of the air admitted (due to the treating of it), did not compensate for the power consumed in working the two air-pumps which forced it into the boiler. At the same time the difference in the useful effect in the two modes of working did not appear to be so great as the power required in handling the pumps led one to suppose it would be. Hence, there appeared an evidence of a certain latent gain which needed only development. To effect this, one of the air-pumps was discarded, and experiments made by means of waste holes drilled through the walls of the remaining one to ascertain what proportion of air admitted to the boiler fully compensated for the cost of compression. And it was found that about 10 per cent of the effective consumption of fluid in the working cylinder gave much more favorable results. At the same time the cam motions were discarded, and the air-pump valves left to their own unaided action. The results are given in the subjoined table:

TABLE NO. II.

Combined Air and Steam Engine.

Coals consumed during experiment	Weight on brake.	Duration of experiment.	Number of revolutions of brake.	Number of revolutions of brake per minute.	Gross H.P. of useful work done.	Gallons of water evaporated during experiment.
lbs. 140	lbs. 124	min. 195	8,463	43.4	551 1	104.3
Steam Engine only.						
lbs. 140	lbs. 124	min. 145	5,942	41	386.9	64

Percentage of gain in work done by combined engine, as compared with that done by steam only, 42½ per cent.

Here, although a very remarkable relative economy was apparent, it became obvious, on consideration, that danger of mistake would arise in assuming this economy as absolute, inasmuch as the duty performed, when contrasted with that obtained from engines of standard types, actuated by steam, was manifestly low, and it seemed probable that, as by judicious improvement in details, the duty was made to approximate more closely to fair steam-engine duty, this relative economy might fall off considerably, inasmuch as there would be less margin to economize upon.

With the view of testing this point, and also for the satisfaction of railway engineers, of conducting experiments at locomotive pressures, a thorough remodeling of the whole apparatus was effected. The tappet motions were thrown aside in favor of the usual slide-valve arrangement, working with a moderate amount of expansive action. The former wasteful vertical boiler was discarded in favor of a more economical one, of the compound or Cornish multi-tubular description, so as to obtain a better evaporative duty from the coal consumed. The radiating surfaces of the cylinder pipes were re-clothed, and the feed-water heated by the exhaust steam. Instead of exposing the air-pipe to the direct heat of the furnace, as in the former case, the air became thoroughly heated on its passage from the pump to the boiler to a temperature of from 500° to 6,000° Fahr., by being conducted through suitable coils and pipes through the exhaust steam in the heater, and the waste heat in the boiler flues and uptake.

The general arrangement adopted is shown by the accompanying drawings. The air is forced by the air-pump through a tube of ordinary wrought-iron, and of 1¼ in. internal diameter, into coils in the regenerator, which is heated by the exhaust steam, thence in a straight line to the uptake, down which it passes through a coil into the flues beneath the boiler, and through another coil in the smoke-box, thence back to the front of the boiler and past the clack valve, and is led down by an internal bend to the bottom of the boiler water space, where it is evenly distributed along the whole length by a perforated pipe, and the results are given in the following tables, Nos. III and IV:

TABLE NO. III.

Combined Air and Steam Engine—Even Pressure trial.

Coals consumed during experiment.	Weight on brake.	Duration of experiment.	No. of revolutions of brake.	No. of revolutions of brake per minute.	Gross H.P. of useful work done.	Gallons of water evaporated during experiment.	Weight of fire left in furnace when engine was stopped.

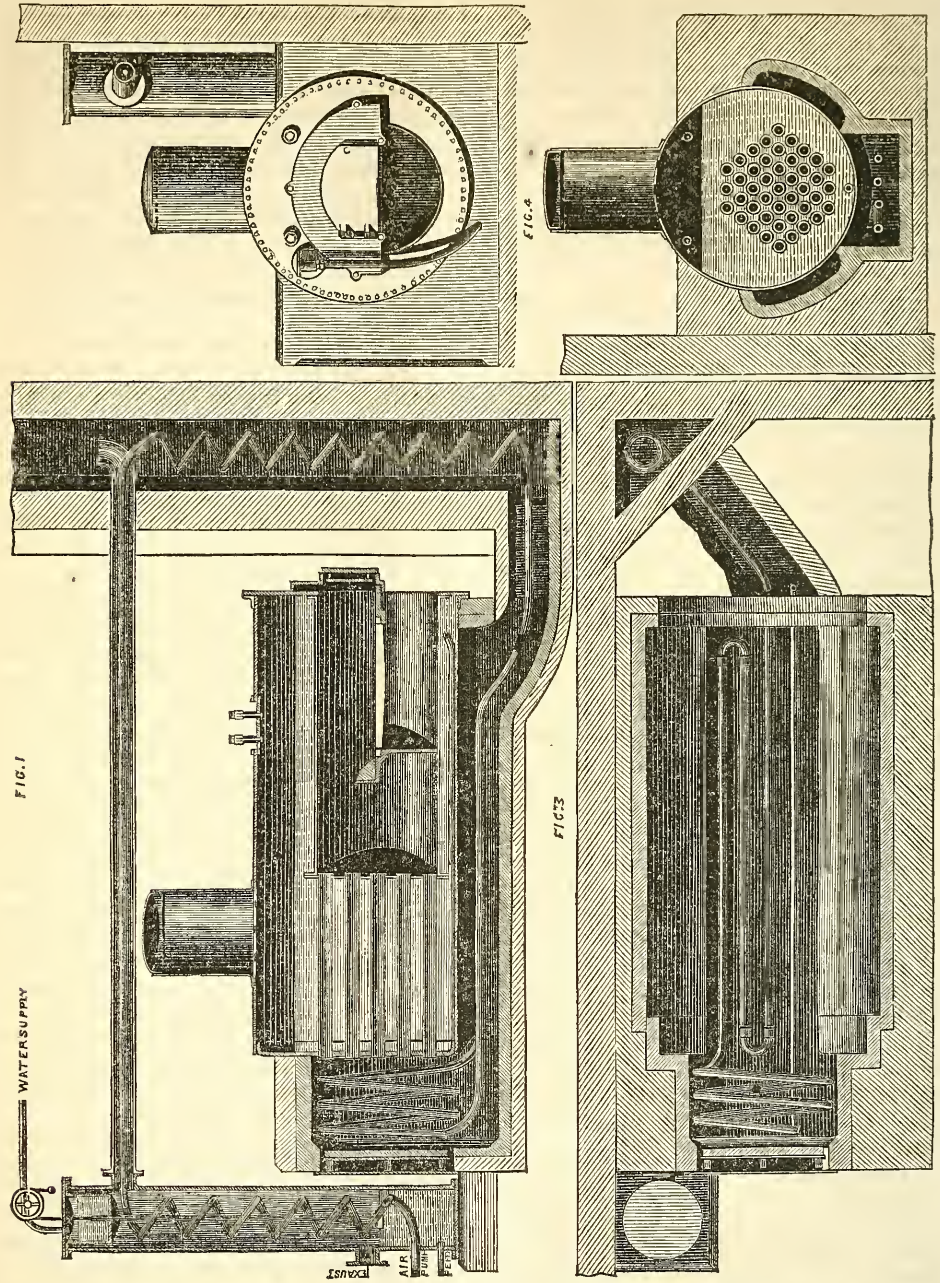
lbs. 140	lbs. 120	min. 196	17,825	90.94	1,115.7	112.5	lbs. 28¼

Percentage of gain in work done by combined engine as compared with that done by steam only, 27.994 per cent.



The pipe through which the air is forced into the boiler by the action of the air pump is of iron, and is $1\frac{11}{16}$ in. in diameter outside, and $1\frac{1}{4}$ in. bore. On leaving the pump the pipe is first led to the heater, shown on the left of the engraving, wherein it is exposed to the exhaust steam. The heater consists, as will be seen, of a cast-iron cylindrical vessel placed in a vertical position, and provided with two branches—one near the bottom and the other near the top—through which the exhaust steam respectively enters and escapes from the casing. At the top of the heater is placed a small cylindrical tank exposed at the bottom and sides to the exhaust steam, and perforated around the upper part of the sides, so that in the event of its receiving an excess of water, the latter may overflow and fall to the bottom of the heater. Through a stuffing-box at the bottom of the tank there passes a tube provided with a rose at the lower end, this tube being carried by a float, which swims in the water at the bottom of the heater, as shown, and, by means of a cord passing from the top of the tube, works a cork, which regulates the supply of water to the tank at top of the heater. The action of this heater will be readily understood without further explanation, and we need merely add that it furnishes a steady supply of hot feed-water at a temperature of from about 195° to 200°.

The air-pipe, after leaving the heater just described, passes along the exhaust pipe to the chimney, and descending the latter spirally, as shown, passes into the flue beneath the boiler. Here it is led backwards and forwards, as shown in the plan, and after making several convolutions in the smoke-box, is led back to the front of the boiler, where it communicates with a valve-box containing an ordinary light clack-valve. The object of this valve is to prevent water from entering the air-pipe when the engine is stopped. From the valve box a pipe is let down within the boiler to the bottom of the latter, this pipe being perforated at intervals on the upper side. The perforations are placed closer together at the further end of the pipe than they are at the end at which the air enters, and by this means an equable distribution of the air at the different parts of the boiler is insured.

The lengths of the various portions of the air-pipe are as follows: In feed-water heater 12 ft.; in exhaust-pipe 13 ft. 6 in.; in chimney and flues, including coils in smoke-box and under boiler, 58 ft.; total, 83 ft. 6 in. The total external surface exposed by this pipe is thus about 36¾ sq. ft.

The principal dimensions of the boiler are as follows: Length, 8 ft.; diameter of shell, 3 ft. 6 in.; diameter of fire-box flue, 2 ft. 2 in.; length of fire-box and combustion chamber, 5 ft.; and length of tubes, 3 ft. The tubes are 41 in number, most of them being $2\frac{5}{8}$ in., and some of them $2\frac{5}{16}$ in. diameter. The total effective heating surface exposed by the boiler is about 130 sq. ft.

It is right to mention that in all the before detailed experiments, the "Prony" brake with the best modern improvements was used as the measure of useful work done, and *every care* taken in the conduct of these trials to determine accurately the amount of water evaporated, and the duty done in useful effect by a given amount of fuel.

Other observations as to temperature, indicator diagrams for determining the cost of the air compression in proportion to the power developed, and various useful notes were obtained, which it would be out of place to recapitulate here at length, but all these details are at the disposal of the Association, or any scientific persons interested in the subject.

Professor Tyndall has volunteered to investigate the scientific bearings of the results which have been personally observed in Nottingham by that accomplished amateur engineer, Lord Richard Grosvenor, and by other engineers, several of whom have already applied to be licensed to make.

It remains to submit to your consideration the theory of our system. We have here a machine which, when worked as an ordinary steam engine and boiler, performs as respectably in its brake duty as an average well-constructed commercial engine, not designed to work with a high rate of expansion, and we find that the addition of the pneumatic arrangements considerably enhances the amount of its useful duty.

Let us now endeavor to ascertain in what manner the gain in question arises, premising that the following condition of things can exist only in theory. Suppose a boiler to be theoretically perfect, wasting no heat, and its feed level maintained only just constant, the quantity of water evaporated being infinitely small, and friction of all kinds to be eliminated in the machinery. Then the power required in compressing any given amount of air at atmospheric density will be recouped by the power generated by the re-expansion of the air so condensed, action and re-action being equal.

Let us now ascertain the cost of obtaining a given quantity of steam at a given pressure, as compared with the like quantity of air at the like pressure, and for the sake of example we will take 150 c. ft. in each case at 60 lbs. pressure per square inch in gauge. Here the relative volume of the steam to the water which generated would be in the case of 60 lbs. pressure (307° Fahr., about) = 355 to 1, according to Regnault. And it follows that the 150 c. ft. of steam under consideration was generated from 1.355th of its volume of water originally, or .422 c. ft.

The weight of one cubic foot of water being 62.32 lbs., the weight of .422 c. ft. would be 26.3 lbs. Now, to raise 1 lb. of water from 62° Fahr. to 212°, or through 150°, requires 150 heat units; to convert it from water at 212° into steam at any pressure, 966 heat units; total gross units, 1,116; and as the conversion thus of 1 lb. of water requires 1,116 heat units, it would follow that the conversion of 26.3 lbs. of ditto would require 29.350 heat units, which is the cost of obtaining 150 c. ft. of steam at 60 lbs. pressure. In the case of the air, 500 c. ft. of atmospheric density and temperature, 62° would, by Mariotte and Dulong's law, be transformed into 100 c. ft. at 60 lbs. per sq. in. on gauge, supposing the temperature remained unchanged. But this 500 c. ft. of atmospheric air is, by the combined agency of the increase of temperature, due to compression and the application of artificial heat in some form brought from its original temperature of 62° up to that of the boiler, viz: (that due to 60 lbs. pressure,) 307°; in other words, through 245° Fahr. Now, the weight of 500 c. ft. of atmospheric air = 38.05 lbs., that of 1 c. ft. at atmospheric density and 62° temperature being = .761 lbs., according to Regnault's experiments. And we have seen that this 500 ft. at atmospheric density, and 62° temperature, is equivalent in value to 100 c. ft. at 60 lbs. pressure and the like temperature, the weight therefore would be alike = 38.05 lbs.

The increase of volume from 100 c. ft. due to the increase of temperature from 62° to 307°, or through 245° would be, according to the general formula applicable to the expansion of gases, about 50 per cent, or, say roughly, as the volume would increase 1-480th of its bulk for each degree Fahr. increase of temperature; for 245° increase, the original bulk, 100 c. ft., would be increased 245-480ths, which is about 50 per cent, the original 100 c. ft at 60 lbs. pressure per square inch now becoming 150 at the like pressure, and this weighing 30.05 lbs. The number of units of heat which will be consumed in raising the temperature of this 38.05 lbs. of air from 62° to 307°, or through 245°, the pressure remaining constant and the volume variable, as above described, will, according to Regnault, bear the same to that which would raise the same weight of water through the same amount, as 238 to 1.

38.05 lbs. × .238 × 245° range through which raised = 2,218.69 heat units, which is the cost of obtaining 150 c. ft. of air at 60 lbs. pressure, as compared with the 29,350 heat units before mentioned in the case of the like quantity of steam, a very striking and remarkable difference. Both these 150 c. ft. are capable, when worked in a cylinder, of generating the same motive force, and are alike capable of being worked expansively, but it is an important consideration whether the loss in working the air expansively would not be greater, owing to its more rapid radiation and loss of heat and consequent loss of volume and pressure.

A further series of experiments are about being made with the view of ascertaining the results due to working at higher pressure and rates of expansion, and here thorough jacketing and maintenance of the temperature of the working cylinder will doubtless prove most valuable.

Such a theoretical gain, viz: about 13 to 1, is evidently vastly far from being realized in the experimental engine, seeing that only about 13 per cent of the whole cylinder consumption in the last experiment is passed into the boiler (in place of 100 per cent, as in the investigation above given), the remainder being supplied by the steam generated, thus 13 per cent air + 87 per cent steam; and we must look to other causes, in addition to the above, to account for the economy realized in practice. It is conceived that it is to the injection of air into the boiler that this may mainly be referred for the following reasons. When steam is ordinarily raised from water, the heat expended is consumed partly in overcoming the cohesion of its particles, and in creating steam room for the vapor raised, and, further, in promoting the circulation of the water itself in the boiler. In all of these operations work is done, and the injection of the air accomplishes practically the work which, under the above mentioned circumstances, would have to be done by the heat, a much more intense and rapid circulation of the water is achieved, and the rapid ebullition and giving off of steam bubbles is greatly promoted. Further, the air enters at a high temperature, and its *direct* action upon the water is equivalent to an increase of evaporative surface, all the more efficient from being direct instead of communicated by the conductive power of metal plates. It is to be regretted that some more certain method than the usual high grade thermometer has not yet been devised and applied for, measuring the temperature of the incoming air, which is the best absorbent of waste heat in the boiler flues, which can well be devised, and, according to present experience, a very perfect agent in transmitting it into mechanical force. In short, the change of condition which occurs in the boiler immediately on the admission of air may be best realized by imagining the tubes and tube-plates to be suddenly removed and replaced by an indefinitely large number of tubes of infinitely small diameter, permeating the water and increasing the ebullition and disengagement of vapor bubbles by an agitation almost mechanical.

An experiment, which has been repeatedly made, goes far to confirm this view. Let the engine be running under steam, the pressure gauge rapidly falling, with the fire fast dying out, the putting the air-pump in gear will cause the gauge to mount several pounds in the course of a few minutes, and there continue for a considerable time, the engine meanwhile continuing to work as before, after checking a moment or two on first feeling the increased resistance due to putting the air-pump in action. And this result evidently shows that the evaporative duty of the boiler is increased immediately on the admission of the air, and irrespective of the state of the fire—a state of things which is consistent with the foregoing explanation, and, indeed, scarcely susceptible of any other.

Even did time permit, this possibly is not a fitting occasion for more than a passing glance at the social or commercial bearings of this discovery. As our navy and Government workshops can thereby be coaled at far less cost than hitherto, taxation may be reduced. Agriculture will be an immense gainer in the impulse given to steam cultivation in all its branches, no trifling consideration in view of the fact that in the month of May last one English firm turned out 102 portable engines. Manufactures of all kinds, where steam-power is used, will be cheapened, the sailing vessels of our mercantile marine will be rapidly transferred into auxiliary steamers able to traverse the Suez canal and the Red Sea, towards which all eyes are now turned. Communication with all parts of the world will be cheapened and facilitated. There are good grounds for expecting that railway dividends will improve. It is estimated, by way of example, that the Metropolitan line would save £6,000 per annum in fuel and water, whilst the ventilation of its tunnels would be improved, and the additional power, gained at a trifling outlay, would enable each engine to draw two more carriages than at present. Our mines, our water-works, our drainage operations, and our quarries will share in the general gain. Our mechanics, now quitting, with weeping eyes and aching hearts, the land of their nativity, because they have no work, will have enough and to spare, through the impulse given to the construction of new engines and the adaptation of old ones. Nor will the colliery-owner suffer, as is proved by the cordial satisfaction already expressed in that direction.

Opportunely does this discovery come in 1869, the centenary of the steam-engine.

A writer, in a recent number of that valuable paper, the "Economist," remarks that "a single improvement, to save 10 per cent in fuel for the steam-engine, would probably add more absolutely to the real wealth of this generation than the invention of the steam-engine itself added to the real wealth of the generation in which it was invented." After years of anxious research we now possess such an improvement, but of greater value. We are thankful for the opportunity of doing good in our day and generation.

THE REMOVAL OF SILICON FROM PIG IRON.

Abstract of a paper read by Mr. J. PALMER BUDD, before the Iron and Steel Institute.

In the Welsh ironworks, the pig iron is principally white. The whole of the forge cinder made is put on the blast-furnaces; and cinder in large quantities is purchased in addition from the tin plate and other neighboring forges. A large admixture of Lancashire and Cumberland and other hematite ores is put on the furnaces as a corrective. The furnaces are driven hard; and the white is of course inclined to be sulphury. The plan of working is to refine, before puddling, from a half to a third of the white in refineries placed before the blast-furnaces, potting the iron into them. The yield of these fineries from molten iron is about 23 cwt. of pig or cast iron to the ton of refined metal; the consumption of coke is 5 or 6 cwt. to the ton; and the total expense of the refinery process from 10s. to 15s. a ton. In some works the puddling furnaces have one-half white pig and one-half refined iron; in others, the proportion is one-third refined metal, one-third white pig, and one-third mine pig, made without cinder from argillaceous mines and hematite ores. Soft Lancashire ore is freely allowed for fettling the puddling furnaces. The popular notion is, that the white iron is decarbonized in the refinery process, and freed from sulphur and phosphorus. Messrs. Crace Calvert, and R. Johnson, Dr. Percy, and other authorities, have shown conclusively that this popular notion is unfounded. They have proved that all cast iron contains a notable proportion of silicon varying from 1 to 6 per cent (the grayer the iron the greater the proportion of silicon), which is reduced in the blast-furnace, and combined with the iron from its earthy base, silica.—It is silicon which imparts its casting property to pig iron; when removed, cast iron is only semi-fluid, although it may retain all or nearly all its carbon. From its greater affinity for oxygen than carbon, silicon protects the carbon in pig iron from the action of oxygen; even when it is present in the small proportion of 1.500 per cent no carbon is burnt off. Silicon is, in many of its properties, very analogous to carbon; and the refining process instead of being called a decarbonizing, might be better described as a desiliconizing of the iron. Now, the process he had invented desiliconized the iron as tapped from the blast-furnace without wasting the iron, and without any extra expense whatever beyond the usual cost of the pig; nay more, it was more economical to make than pig iron. The process must therefore revolutionize the present practice in the iron trade. His usual mode of proceeding was to place a series of iron moulds similar to those used before a refinery, as near as convenient to the top hole of the blast-furnace. He made a paste by moistening with water soft hematite ore, which, if gritty, is previously ground, and he threw a bucketful, containing about 60 lbs., into the mould in a semi-liquid state, and spread it evenly on the bottom and sides. The mould being quite hot from the previous cast, dries the paste, which adheres to the bottom. He then pots as much iron as is required from the blast-furnace, and allows it to run over and fill the moulds to the depth of three and a half to four inches. A great ebullition took place; jets of flame of a peculiarly white color burn on the surface, which he assumed to be the combustion of silicon in the oxygen abstracted from the hematite. It was proved by repeated analysis that whilst the silicon was 1 per cent in the white cast iron, it is reduced by this simple process to .200 to .300 per cent, or from 1 per cent to 1-500th, a cinder is thrown up containing silicon, some phosphorus, and sulphur. The carbon is hardly at all removed. The appearance of the iron after the process is that of refined metal.—For want of a sufficient upward impulsive force, a good deal of the scoriæ, although chemically separated in the process from the iron, is not removed from it mechanically, but is mixed with the refined metal; and, on remelting in a puddling furnace, forms a protecting slag. The cost of the process is nil, as the iron contained in the hematite is reduced, and adheres as cast iron to the bottom of the iron in the mould. There is no sand or coke dust used; and the refined iron goes clean into the puddling furnace. The yield in puddling is, that of refined iron, about 21 cwt. to the ton of puddled bars.—The puddlers like to have one or two pigs of white, with the metal so refined, as they say it works more "liquory"—showing that when the silicon remaining is only .200 or .300 per cent, the charge does not possess the necessary fluidity. The puddling furnace keeps longer in repair; no other fettling is used; and hammer slack and the former allowance of shearings to make scrap balls has been discontinued. The men do more regular work; and, like the refined iron, the yields are larger. The puddled iron is of an improved quality, and much liked in the rail mills. The second process was the same as the first, only that he mixed two-fifths by weight and half by bulk of nitrate of soda with the hematite ore, which is formed into a paste, and applied in the same way. With this mixture, the ebullition is greater; the flame is of a yellowish color—showing the ignition of some of the soda. The cinder is thrown up and out of the iron, over which it forms a crust, which can be separated when cold. The iron has a cellular and honey-combed fracture, like metal much over-blown. The scoriæ contain sulphur, phosphorus, silica and soda. The iron works drier and cleaner, and to a better yield than that made by process number one, but should have about one-third of gray pig added to make a very clean and rough iron. The only cost of the process is the nitrate, which in the proportion named comes to about 4s. per ton at its present high price. The saving by the process was very considerable, and it was not confined to white iron, though it was then most efficacious. The author added: "In my opinion, the money value of my invention to the iron trade will be enormous; greater, perhaps, than that arising from the use of the blast-furnace gases, said to be a £1,000,000 a year, and which I first introduced into this country and made known to the iron trade at the meeting of the British Association held at Swansea, in 1849."

ASPHALTED SURFACES.

From the "Mechanics' Magazine."

A mixture of the ordinary coal gas tar and common gravel constitutes nine-tenths of the so-called asphalte, and it is no wonder, when the spurious article is passed off for the genuine, that the latter suffers in the estimation of the public, and many refuse to believe in the durability and efficiency of an asphalted surface. This is the natural result of the very cheap and very bad footpaths and platforms that have been laid down in numerous localities and composed of the ingredients referred to. A surface thus constructed will, in spite of the imperfect nature of its components, if the formation of it be carefully attended to exist for a time in a smooth and apparently sound condition. This appearance is, however, deceptive. The influence of wear and tear, combined with the action of wet, speedily produces hollows and irregularities, cracks and crevices extend their ramifications in every direction, and the opposite effects of heat and cold are equally active in the work of disintegration and destruction. The one renders it sticky in summer, and the other brittle in winter; the whole mass soon breaks up and has to be removed, to the loss and disgust of those who laid it down, and who register a vow never to employ "asphalte" again for any purpose whatever. If we now consider the difference between the spurious and genuine articles, it will not be surprising that the former has no claims to the title that belongs properly to the latter. Instead of being the hasty result of a mixture of tar and sand or gravel, the genuine asphalte has a very different composition. Its chief ingredient is derived from a natural production, drawn from foreign quarries, or mines as they are generally termed. At present, there are very few of these mines, of which the best known is probably that of Pyrimont. The raw material arrives in the form of dark-colored amorphous lumps containing a large proportion of bitumen, which is extracted by the employment of suitable mechanical means. One of the principal components of bitumen, according to the nomenclature of M. Boisingault, is the substance asphaltene. It has a chemical composition represented by the formula $C_{20}H_{16}O_3$, and we recommend it to those whom it may concern as an excellent name whereby to distinguish the genuine from the spurious article. When it is kept in view that, in order to obtain a material fit for manufacturing asphalte as it ought to be made, it is necessary to import the chief ingredient from Italy, it is evident at a glance that there will be a wide difference in the price of the foreign and the home production. As the price, so is the quality. A permanency and durability are obtained by the use of the extracted bitumen which cannot be expected from the wretched stuff prepared from the ingredients to which we have alluded. At the same time, it is equally necessary to ensure good and sound workmanship in the laying down of asphalte as to provide the best materials. There is a company which has portable machinery, especially designed and constructed for this purpose, which allows of a large area being covered in a comparatively short space of time. As we have deprecated the use of bad and inferior asphalte as exceedingly deceptive to the public, and prejudicial to the prospects of the only proper substance, it is but fair to give a few instances where the latter may be seen and its value appreciated. One of these is, in the words of Mr. Hepworth Dixon, "Her Majesty's Tower." Most of the footpaths, and some portions of the roof, have been laid for some years past with Pyrimont asphalte, and yet present no signs of deterioration. The roof of the new prison at Holloway, and the extensive footpaths around the fountains in Trafalgar-square, are other examples.

According to the climate and the purposes for which it may be intended, so can the composition and character of asphalte be varied. From its nature, it must always possess some little elasticity, even when that quality is required to be reduced to a minimum. This is one of its properties, which is frequently of considerable advantage. It renders it exceedingly valuable as a "damp" course in buildings, and much superior to slates, tiles, concrete, or other hard and unyielding substances. Considering them all on a par with respect to water-proof qualities, the asphalte alone possesses the capability of yielding to any local pressure. Consequently, if any portion of the foundation settle, the slates, tiles, or other hard substances at once break across, and the watertight continuity is destroyed. The asphalte, on the contrary, adapts itself to the settlement of the foundations, and preserves the water-proof layer intact. Any one who has walked over a large area of properly executed asphalte cannot fail to ask himself the question, whether its application could not be extended to road and street traffic. There is no doubt but that the substitution of asphalte for granite or macadam would be hailed with ecstatic delight by the riders of bicycles. What a road to run on! A portion of Threadneedle-street has within the last nine months been laid down with asphalte, but upon a different principle to that upon which footpaths are constructed. Some time must elapse before it will be possible to judge of the suitability of this surface for the severe tax made upon its powers of resistance and durability by the exigencies of our metropolitan traffic. There is another situation for which an asphalted surface appears to be well adapted, and in which its property of elasticity can be advantageously brought into play. It is in the case where it is necessary to form a footpath on made ground. The most extensive example of this kind is probably to be found in the foot thoroughfares of the Thames Embankment, and any one who is in the habit of traversing that on the north side cannot fail to perceive how badly the paving flags adapt themselves to the irregularities caused by the "giving" of the ground underneath. A very slight subsidence, which would be scarcely appreciable under ordinary circumstances, is quite sufficient to destroy the evenness of a flagged footway. As it is, many of the flags are disturbed to an extent which throws up one end fully an inch above its neighbor, and imparts a very jagged appearance to the surface. Taking them up and relaying them is the remedy, but how often this remedy will have to be repeated it is impossible to assert, for railway experience has demonstrated that it frequently requires a long time for a heavy embankment to settle permanently to its "bearings." In pointing out the manner in which paving flags behave under the conditions in question it is not intended to assert that they ought to be replaced wholesale by an asphalted surface, but had a small portion of the Embankment been covered by the latter substance, the relative merits of the two descriptions of paths would have been fairly and impartially tested. The principle of giving every method of executing any particular description of work a fair trial is one that needs urgent adoption by the various branches of our civil and military departments. By every method is signified every one that possesses manifest claims to consideration, and does not, of course, include the mere ideas of inventors, or hobbies of patentees which are destitute of all practical utility. But, when an individual or a company is willing to test, solely at their own expense, any plan they consider likely to effectually accomplish any desired object, they ought to be allowed to have an opportunity of so doing. It might be urged that the public ought not to be put to any inconvenience with respect to interruption of the ordinary traffic, supposing the trial concerned the taking up of any part of a street or thoroughfare. What with gas and water companies who are perpetually breaking up the streets, the public is pretty well used to such inconveniences. Moreover, as the object of all proposed improvements is to benefit the public, the end fully justifies the means. There are undoubtedly many valuable inventions totally lost to us solely because we never permitted them to be fairly and dispassionately investigated, and their practical merits submitted to the crucial test of actual experience.

SIEMENS' REGENERATIVE FURNACES.

Abstract of paper read by Mr. Josiah T. Smith before the Iron and Steel Institute.

Although, the writer said, this subject had been brought before various societies since 1862 by some of the most eminent men of the day, and for many years had been in extensive and successful operation in various processes connected with manufactures, both at home and abroad, it had, with very few exceptions, not been adopted in the iron and steel works of Great Britain. It was possible, however, that in a few years those districts which contained large quantities of inferior coal or fine slack, without sufficient bituminous principle to make it available for cooking purposes, would find that they possessed, by means of the above invention, the opportunity of supplying their requirements from such sources. While in this country it was probable that coal would exclusively be used to produce the gaseous fuel required for the regenerative furnace, in France, Belgium, and Spain they merely used wood; in Germany lignite, and peat in Italy. It was believed that the first idea of storing waste heat to be used at intervals was due to Dr. Stirling, of Dundee, who, in 1817, patented the regenerator or heat accumulator, and subsequently applied it to his caloric engine. Captain Ericsson, in 1851, also used a kind of regenerator to his air engine; but Siemens had previously, in the years 1847-8-9, taken out patents for his regenerative steam engine and condenser. None of these inventions ever came into extensive practice, and not till 1862 did the discovery really assume a shape which was at all attractive. The invention might be generally described as requiring a producer—for the volatilization of coal, wood, peat, and such like products into gases—which might be erected at any practicable distance from the furnaces to which they were to be applied; while a regenerator, divided into four compartments filled with loose fire-bricks, had to be placed under the furnaces. These regenerators were simply fire-brick chambers divided into four compartments, one on each side for the passage of gas, and two in the centre for air, with generally five ports at each end communicating with the furnaces above. The chambers were filled with fire-bricks placed in a chequered manner, and while the upper portion had to be of the best quality, those beneath would answer if they were of the most inferior description. The chemical action which took place in the producers was described by Mr. Siemens in his lecture before the Chemical Society as follows: "Air is admitted at the grate and as it rises slowly through the ignited mass, the carbonic acid first formed by the combinationof the oxygen with the carbon of the fuel takes up an additional equivalent of carbon forming carbonic oxide, which, diluted by the inert nitrogen of the air, and by a little unreduced carbonic acid, and mixed with the gases and vapors distilled from the raw fuel during its gradual descent towards the grate, is led off by the gas tubes to the furnaces." The temperature of the gas at the junction of the upcasts with the tubes was 1,250 to 1,300 degrees Fahrenheit, a rather higher point than had yet been noticed. Before it had traveled 200 ft. in the tube, with an external atmosphere of 60 degrees, the temperature was reduced to about 130 degrees. He had himself been unable to ascertain the exact quantity of heat lost by radiation in the interval, but the experiments, although not complete, were sufficient to show that the quantity was so small that at present he could see no way of economically applying it. This lowering of the temperature and condensation of the gases was of advantage in many respects. The gas being heavier, caused, in its transit through the tubes and the various downcasts, a syphon action; and thus not only drew the gas from the producers to the furnaces, but, by keeping up a slight outward pressure, prevented the admission of air through any crevice in the tubes or the expansion boxes. It also deposited the tar from the coals into a series of wells beneath; while the water in the fuel was also condensed, and thus prevented from causing a waste of metal by introducing a too great supply of oxygen into the furnaces. After noticing more in detail the application and effect of the gases, Mr. Smith added that for many months each producer at Barrow had volatilized 3 tons of coal per 24 hours, and that the greatest economy effected was when the consumption had not exceeded 50 cwt. Estimating the weight of one cubic foot of gas at the ordinary temperature of thin air to be .075 lbs., the volume of carbonic oxide, hydrocarbon, and hydrogen, from one ton of coal would be about 53,000 ft.; and the volume of nitrogen about 122,000 ft., or making together a total of 175,943 ft. The consumption of coal in the producers at Barrow being 500 tons per week, it gave an amount of gas passing through the tubes at the rate of 6½ ft. per second, of 87,000,000 cubic feet; or through the various furnaces, adding the quantity of air there admitted, of 6,600 tons. The saving of fuel by this process at Barrow was, over a period of two years, no less than 44 per cent; but the actual money saving, by the use of a particular kind of coal, had been more than one-half. The yield of the gas furnaces, taken over the same period, showed a saving of 31 per cent as compared with the work at the firing furnaces, and the amount of repairs was just two-thirds of the old cost. In these three particulars was undoubtedly to be found the chief economy; but the adoption of the system enabled them to preserve greater cleanliness and order in their works, and an entire absence of smoke met a difficulty which in the neighborhood of large towns, was every year becoming a greater grievance. There was, he admitted, a slightly increased outlay on the plant; but taking into consideration the increased capabilities as to quantity, it would be found to represent the difference in cost between the two systems.

RAILWAY WORKING.

From "Engineering."

A given line of railway has, say, 5,000 passengers, on the average to be carried daily. Whatever pair of factors of this number be taken, one represents the number of passengers per train. There may be ten trains with five hundred passengers in each, or five hundred trains with ten passengers in each; or, intermediately, fifty trains with one hundred passengers in each. As for "railway economy" there can be no question as to which of these three divisions of daily traffic would best pay the shareholders, but it is equally clear that the ten trains, of five hundred passengers each, would not suit the imperative requirements of public convenience. The passenger wishes to hail a train much as he would hail a cab. Nothing would suit him better than to have it all to himself, or to himself and his friends. So there must be a compromise somewhere. It will neither do to run a train, or even a special carriage, for every passenger who has an important engagement, and who must, or thinks he must, be off at once, nor will it do to keep equally impatient passengers waiting for even an hour so that five hundred may be packed off together. Somebody has put forth a pamphlet, from the manager's and shareholder's point of view, arguing that fewer and better filled passenger trains are essential to the recovery of railway property. The Times comes down promptly upon it, arguing, in substance, but with perhaps less force, that passengers must have trains in waiting for them whenever they happen to want them, and that if A finds it necessary or convenient to go at 11 a.m., B has a right to a train for himself at 11.5 or 11.10, and C, if not prepared to go with either, should have his train at 11.15 or 11.20. To all this we heartily agree, merely premising that A, B, and C should respectively pay for their special trains, or club the cost with their friends, desiring to enjoy their society *en route*. It is not, of course, the business of a railway company to provide passengers for every train, but conveyance merely. The passengers must come or stay away, as they choose.

But without pursuing this line of thought, it is almost needless to say that the present system of railway rolling stock is designed for long, well-filled, and, therefore, heavy trains, and this merely because such trains must occasionally, although not often, be taken. The resources of a railway company must never break down, and the engine which draws its six carriages for twenty-five out of twenty-six week days in a month must be able to manage twenty or thirty at nearly the same speed on the single remaining day of the calendar. It might be supposed that two engines could be employed for the long train, or that the train might be broken in two, with an engine to each half. But this is not the custom.

Cannot frequency of trains, however, and corresponding public convenience, be attained with rolling stock especially adapted for a given service, meaning by "service" the conveyance of a definite maximum number of passengers at a given speed? If one hundred passengers are to be taken they may as well be taken in one as in three or four carriages, although it is not to be forgotten that, with three classes, the twenty-four first class, the thirty seconds, and the forty thirds may not arrive in the exact order to which the wisdom and liberal provision of the designer and carriage builder may have designed them. There may be forty firsts, twenty seconds, and no thirds; or, possibly, no firsts at all, ten seconds, and a hundred and sixty thirds. If we could but arrive at the democratic equality of the American carriages—not that any one wishes it—we might manage the whole hundred of the company within as many seats.

But, taking our ideal, if, indeed, it be not a fair average real train, we should require ten compartments, if not eleven, and, if we say ten, between 50 ft. and 55 ft. in length for the compartments alone. As compartments, filled with passengers, they would not weigh beyond 15 tons—of course, irrespective of the springs, axle guards, axles, and wheels beneath. Now, what power is requisite to draw this weight, say upon average gradients of 1 in 100 to 1 in 200? The least calculation will show the power to be so small that a "modern" locomotive looks abominably huge and heavy in comparison. Upon the double bogie plan the ten compartments may readily be comprised within a single carriage, and at one end, at least, the carriage would be supported upon the engine (Fairlie's plan), leaving only a four wheel or six wheel bogie to support the other end, a bogie weighing, perhaps, three tons. The engine, proper, would then require to be of such power as would draw 18 tons only in addition to its own weight. Upon gradients of from 1 in 250 to 1 in 100, this weight, at 30 miles an hour, would involve a tractive resistance of but from 480 lbs. to 920 lbs. It is evident, from the very extent of these resistances, that a tank engine of ten tons' weight would be sufficiently strong to overcome them as well as its own resistance, or, say, 28 tons in all, giving an average resistance on gradients of, say, 1 in 140, amounting to less than 1,000 lbs., which, at 30 miles an hour, would correspond to 80 horse power. With a pair of 9 in. cylinders, 15 in. stroke, and four coupled 5 ft. wheels, this resistance would require a mean effective pressure of a little less than 50 lbs. per square inch upon the pistons throughout their strokes, while upon a level the necessary pressure would be less than 25 lbs., and the horse power hardly 40, equal to which a good 12 horse (nominal) portable engine is often made to work. Now, with an ordinary 22 ton engine and tender, weighing in all 35 tons—such an engine as is very commonly employed upon light trains, having, say, 14 in. cylinders, 18 in. stroke, and 5 ft. driving wheels—its own resistance at 30 miles an hour on a level is not less than 720 lbs. requiring 12 lbs. mean effective pressure per square inch upon pistons of nearly twice the area assumed for the steam carriage. The engine and tender, or even the tank engine commonly employed upon light traffic lines weighs, on the average, as much as the train drawn, often, indeed, even more.

It need hardly be said that the resistances of engines and trains have been established by numberless experiments, that the resistance due to any given weight is therefore readily calculable, that it is always in proportion to the weight, and that the cost of working, and especially wear and tear, are in proportion to the resistance. With a given line, then, power can be economized and wear and tear lessened only by keeping down the weight, and why engineers should insist as they do in keeping it up we cannot explain. With the bogie, at each end, the single long carriage can be made much lighter than shorter carriages seating the same number of passengers, each carriage having its two ends, its buffers, etc. The steam carriage we have spoken of runs upon eight wheels, with not more than $3\frac{1}{2}$ or 4 tons each on even the driving wheels, whereas the ordinary "train," to accommodate the same number of passengers, would have from 22 to 26 wheels with a maximum load of at least 5 tons on each driving wheel. The long single carriage would be unquestionably the easier of motion, and it has been demonstrated beyond all question by the experiments at Hatcham that it can be safely backed at twenty miles an hour around curves of no more than 50 ft. radius.

We should be sorry to believe in the truth of the charge, so often made, that railway managers and engineers are disposed to set their faces against all improvements out of which they are likely to make nothing for themselves. But we often regret that the salaries of these officers are not more generally made partly dependent upon the economies which they may effect. As it is, the general manager in the receipt of a fixed salary of from £2,000 to £5,000 a year, and the locomotive superintendent in receipt, according to position, of from £800 to £5,000 (and there is *one* case where the latter sum is paid), do not much care to be bothered. And so shareholders lose, and those who would do them real service are, to employ a serviceable phrase, "left out in the cold." But we have hopes still left, and we must find other reasons, possibly less disinterested to the gentlemen in question, if they persist much longer in willful ignorance of what not only *may be* but actually *has been* done in the direction we have pointed out.

STIFFNESS OF THE ROPE.

Written for Van Nostrand's Magazine by Capt. A. Hill, C. E.

On bending a rope over an axle or a pulley, a certain amount of resistance is encountered. This resistance is called the stiffness of the rope. To ascertain by experiment the amount of this resistance, ropes may be bent around cylinders, which are then allowed to roll on a horizontal plane. The difference in the weights which are suspended on both rope-ends, and which produce a slow rolling motion, will, after subtracting the rolling friction, give the amount of this resistance, or determine what is called the stiffness of the rope.

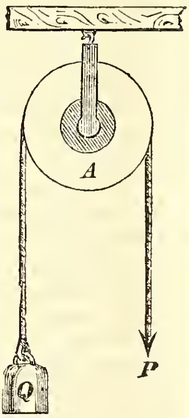
After these experiments, which, however, must not be considered final, the resistance offered through the stiffness of the rope, may be expressed by the formula

$$\delta = \frac{k\,\delta^2}{r} Q,$$

in which Q represents the tension of the rope, r the radius of the cylinder increased by one half the thicknes of the rope, δ the diameter of the rope, and k a co-efficient obtained by experience. For the metric system $k = 18$.

Tarred ropes have always a greater stiffness than untarred ones. Wet ropes, if thin, show a greater, if thick, a less flexibility, other circumstances being equal.

After the previous formula, a rope of two centimeter diameter, bent over a cylinder of four decimeter radius, stretched by a weight of 1,000 kilogrammes, shows a resistance from stiffness of about 18 kilogrammes. A similar result is obtained when a chain is wound round a cylinder. In this case, especially on winding and unwinding, the resistance is occasioned by the friction of the several links. The force necessary to overcome the resistance may approximately be called $\frac{\mu\,\delta}{r}$ Q, in which δ is the diameter of the iron in the links, μ the co-efficient of sliding friction, r the radius of the cylinder increased by one half the diameter of the links, and Q the suspended weight.



Over a fixed pulley A a rope is bent, on the vertical ends of which the forces P and Q are suspended.

How great must P become in order to balance Q and all resistance? Let r be the radius of the pulley increased by one half the diameter of the rope, ς the radius of the pin, δ diameter of the rope, W the weight of the pulley, the rope and the pin, then will

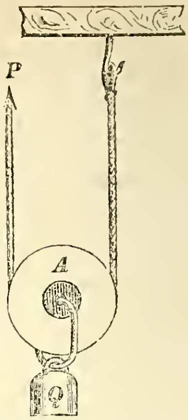
$$P\,r = Q\,(r + k\,\delta^2) + \mu\,\varsigma\,(P + Q + W)$$

whence

$$P = Q\left(\frac{r + k\,\delta^2 + \mu\,\varsigma}{r - \mu\,\varsigma}\right) + W\,\frac{\mu\,\varsigma}{r - \mu\,\varsigma}.$$

Take for example, $r = 0.^m 12$; $\delta = 0,^m 028$; $n = 0.1$; $\varsigma = 0,^m 01$; Q = 200 kil.; W = 5 kil., then will P = 224.24 kil.

Round the movable pulley A, on the pin of which the weight Q is suspended, a rope is bent. How large must the force P become in order to balance Q and all resistance?



Using the same letters for the same quantities, the equation becomes now

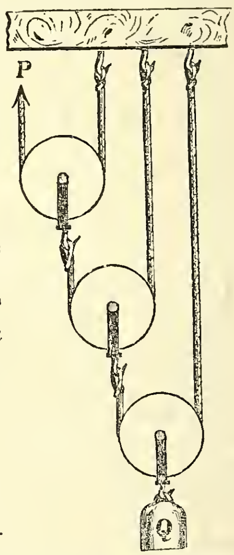
$$P\,r = (r + k\,\delta^2)\,(Q + W - P) + \mu\,\varsigma\,Q,$$

whence

$$P = \frac{r + k\,\delta^2 + \mu\,\varsigma}{2\,r + k\,\delta^2} \times Q + \frac{r + k\,\delta^2}{2\,r + k\,\delta^2} W$$

And substituting the same values as above, we obtain here P = 116.7 kil.

To find P for a system of movable pulleys, when the directions of the rope ends are vertical, and the radii and weights of all the pulleys are equal.



Let ψ, ψ_2, ψ_3 .... ψ_n indicate the tensions of the successive rope ends, and put

$$\frac{r + k\,\delta^2 + \mu\,\varsigma}{2\,r + k\,\delta^2} = a$$

$$\frac{r + k\,\delta^2}{2\,r + k\,\delta^2} = C$$

Then will

$$\psi_1 = a\,Q + C\,W$$

$$\psi_2 = a\,\psi_1 + C\,W = a^2\,Q + C\,W\,(a + 1)$$

$$\psi_3 = a\,\psi_2 + C\,W = a^3\,Q + C\,W\,(a^2 + a + 1)$$

$$\psi_n = a\,\psi_{n-1} + C\,W = a^2\,Q + C\,W\left(\frac{a^n - 1}{a - 1}\right)$$

But

$$P = \psi_n\left(\frac{r + k\,\delta^2 + \mu\,\varsigma}{r - \mu\,\varsigma}\right) + W\left(\frac{\mu\,\varsigma}{r - n\,\varsigma}\right)$$

and making $\left(\frac{r - k\,\delta^2 + \mu\,\varsigma}{r - \mu\,\varsigma}\right) = a'$ and $\frac{(\mu\,\varsigma)}{r - \mu\,\varsigma} = C^1$ we obtain at once

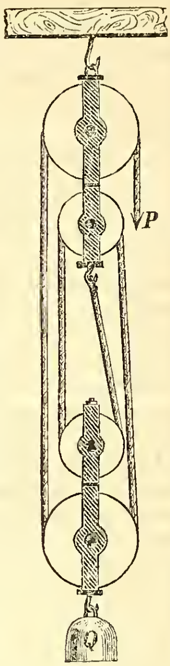
$$P = a'\left(a^n\,Q + C\,W\,\frac{(a^n + 1)}{a - 1}\right\} + C'\,W.$$

Finally, to find P for a system of fixed and movable pulleys, under the supposition that the fixed and movable pulleys are corresponding in size and equal in weight.

Using the same notations as before, we have

$$(a)\ r \times_2 = (r + k\,\delta^2)\,\psi_1 + \mu\,\varsigma\,(\psi_1 + \psi_2 \ldots)$$

in which ψ_1, ψ_2, ψ_3 .... ψ_n represent the successive tensions of the rope, beginning with the fixed end. From (*a*) we obtain



$$\psi_2 = \psi_1 \frac{r + k\delta^2 + \mu\varsigma}{r - \mu\varsigma}$$

or making

$$\frac{r + k\delta^2 + \mu\varsigma}{r + \mu\varsigma} = a$$

$\psi_2 = a\,\psi_1$, and hence
$\psi_3 = a\,\psi_2 = a^2\,\psi,$
$\psi_n = a\,\psi_{n-1} = a^{n-1}\,\psi,$
but $\psi^1 + \psi_2 + \psi_3 + \ldots,$
$\psi_n = Q + W$
in which W equals the weight of the system of movable pulleys.

Substituting in this last equation the values for $\psi_2, \psi_3 \ldots \psi_n$ in terms of ψ_1, we obtain
$\psi_1\,(1 + a + a^2 + \ldots\ldots C^{n-1}) = Q + W$

or $\psi, = Q + W\left(\frac{a - 1}{a^n - 1}\right)$

but since $P = a^n\,\psi_1$. we have

$$P = \frac{a^{n+1} - a^n}{a^n - 1}(Q + W).$$

How to Build.—We read that the builders of ancieut Rome were obliged to warrant their private buildings for ten years, and their public ones for fifteen. Moreover, every accident arising from bad construction during these periods *was to be made good by them or their heirs.* If they were unable to make the necessary repairs, they were whipped, shamed and banished. Some such law like this, if it could be enforced in the nineteenth century, within the bills of mortality of this great city of London, would work a salutary and lasting reform. It is not "how to build," but how not to build; consequently structures are very often, in fact are daily, being erected, whose best recommendation is that they are certain to kill off some portion of every family which may have the misfortune to live in them.

In the first stage of their existence, they effect this by dampness, want of ventilation and the absence of any proper system of drainage. In the second stage of existence of these houses, they kill off their inmates by the presence of too much ventilation. Doors, windows, and roofs exhibit the effects of employing green or unseasoned timber; aching pains begin to trouble the joints and shoulders; and, like the human body, the framing body of joinery creaks with a chronic asthma. In the house where there was insufficient ventilation first, there is any quantity of wind and weather now, for tenon and mortise part company, and paper, lath, and plaster follow suit, with a groan for the internal genii.

The third stage in the life of those model structures is this: that they suddenly drop to the earth with an epileptic spasm, without the least external warning; and in annihilating themselves they bury several families in the one general crash.

Need we add the sequel? Scarcely. We will simply note an "inquest,"—verdict, "accidental death." Not a word of censure on the "jerry builder" or sham contractor, who made a nice thing out of speculating in the blood of his fellow beings. Not a word of reproof on the man that "did not want any of your confounded architects." Not one word on the jack-of-all-trades who was surveyor, engineer, architect, and all. No, not a word. He, like other "lucky dogs," caught up the "tip" of the day, and his trade is to build to *sell*, and not to build to *last.*

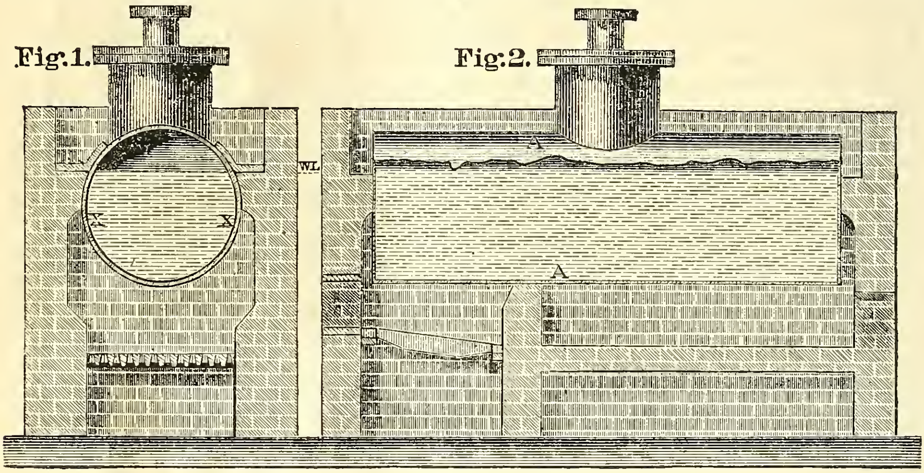
Oh, would that the old Roman law were still in force, or that a vigilance committee were embodied so that the building ghouls of London could be "whipped, shamed and banished" from the country!—*Builder.*

Engine Cranks Cast from Steel.—Messrs. Vickers, Sons & Co., Sheffield, have turned out the second of two of the largest steel cranks ever made, and these cast direct to shape, and not as an ingot.—Its weight, as cast, was 38,500 lbs., or about 17 tons 4 cwt. Five hundred and fifty crucibles were poured, in regular order, in making it. Steel castings have shown surprising and uniform cohesive strength and toughness. They are unquestionably free from any internal flaws or defects of any kind. A cast-steel engine crank, especially of large dimensions, is more likely to be sound (apart from the greater strength of steel *per se*) than a heavy wrought-iron forging of the same shape. Even in wrought-iron forgings presenting no visible or definite flaw, sections cut out and tested have been found to bear no more than 7,000 or 8,000 lbs. per sq. in. The strength of steel, on the contrary, would not vary much from 70,000 lbs.—a strength attended with great toughness or endurance when exposed to sudden shocks.

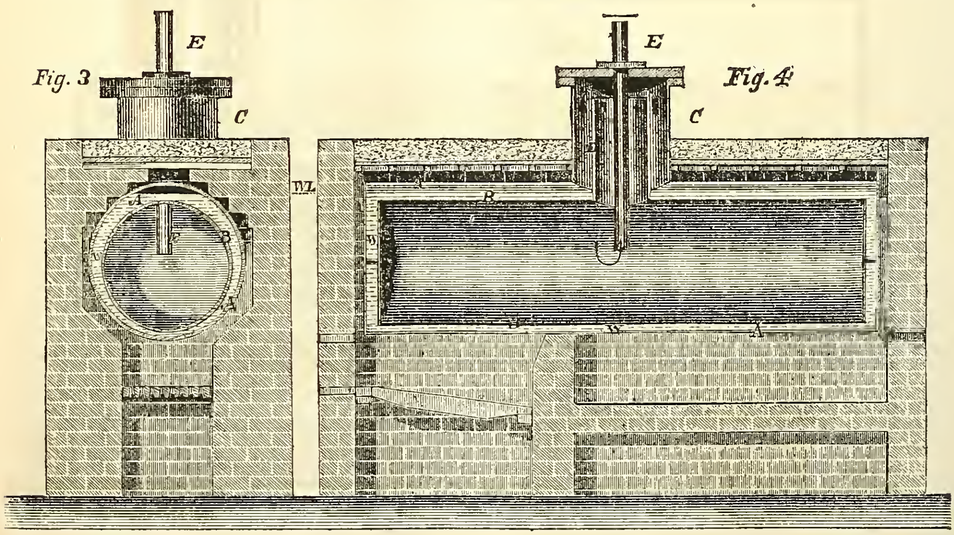
THE GERNER BOILER.

This form of steam generator having now been in actual service for a sufficient time to warrant definite conclusions, and having been subjected to a variety of tests, has developed some notable advantages in working and maintenance, and is attracting a great deal of attention among the users of steam. The accompanying engravings, prepared for this magazine from the latest working drawings adopted, illustrate the different forms of service to which the Gerner principle of construction has been applied. The description and working results are given on the authority of the "Scientific American."

The inventor of this boiler, starting with the assumption that, so far as safety alone is regarded, no form of boiler is superior to the old-fashioned cylinder, has proceeded step by step to develop its steam-producing power without relinquishing its known elements of safety. Figs. 1 and 2 show an end and side view of a plain cylinder boiler, set in brick-work, the space from X to X, around the lower section of the boiler, showing the extent of heating surface. Figs. 3 and 4 give two views of the same boiler, with its power and economy increased by the application of the Gerner Re-inforcement, an application that may be made to any plain cylinder or flue boiler.



Common Cylindrical Boiler.



The Common Cylindrical Boiler with the Gerner Reinforcement attached.

The Gerner Re-inforcement consists in placing within a cylindrical boiler another cylinder of just sufficiently smaller size to leave a space (when set a little out of center) of about 4 in. at the bottom and ends, increasing gradually to about 6 in. at the top. This cylinder, by displacing the large mass of water, as shown in Fig. 2, reduces it to a thin sheet, which fills the space between the two cylinders, and entirely surrounds the inner one; the water line being now near the top instead of the middle of the boiler. The inner cylinder is simply supported at each end by a bracket attached to the outer boiler, and is provided with a dome, open at the top, standing within the dome of the outside cylinder. The steam, as it is generated, rises, as shown by the arrows in Fig. 4, into the outer dome, and thence passes by the inner dome into the interior of the inner cylinder, which thus becomes a large steam reservoir entirely filled with dry steam, which is kept in its normal condition by the jacket of hot water which surrounds and protects it from radiation, the temperature which protects being the same that produced it. The steam-pipe E acts as a steam-trap to convey only dry steam. It will be observed that the pressure of the steam within the reservoir equalizes that of the steam in the water outside, thus obviating the necessity for "staying" and the use of heavy iron in its construction. The water being carried so high in the boiler admits of the brick-work being set off from it, and the fire thus carried entirely around it, throughout its entire length and ends, thereby

Fig. 5.

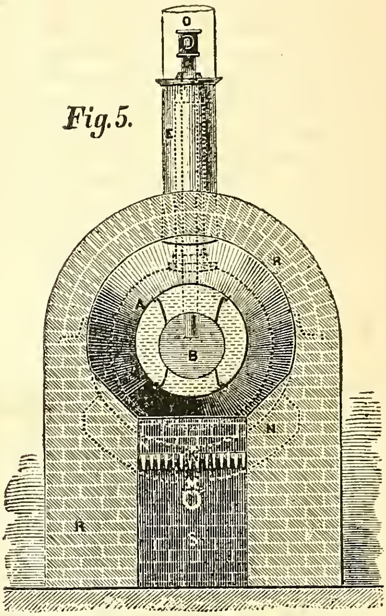


Fig. 6.

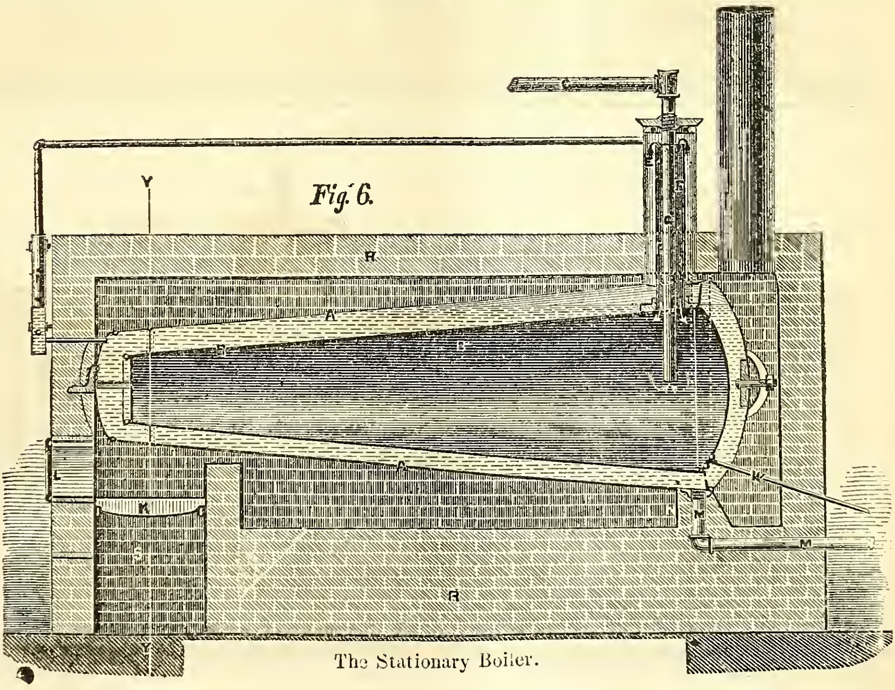

The Stationary Boiler.

doubling the extent of heating surface. The brick-work may be thrown in an arch over the boiler, or the successive layers of brick "stepped in" like a reverberatory furnace, as shown in Fig. 3. It should also be observed that the lessened volume of water materially increases the safety of the boiler. C. Wye Williams, in his able work on "Heat and Steam," page 171, asserts that "the risk of explosion is greatly increased by the increase of water in the boiler, every cubic foot of which, beyond what is absolutely necessary for the generation of steam, being an additional source of danger."

The Stationary Boiler.—Figs. 5 and 6 represent the usual form of the Gerner stationary boiler. The shell is cone-shaped, its smaller end being over the grate; the axis is set level. The flame envelopes the boiler, and its escape is checked at the top and sides by a brick partition at the rear, and its exit is through a vent underneath the larger end of the boiler into the flue and chimney. Within the shell is placed a similar cylinder of less dimensions, leaving an annular water space of about 4 in. at the bottom, and 6 in. at the top.

The angle of the heating surface, as here presented to the action of the fire, is best calculated to catch and absorb the heat, impingement being more direct and effective, while the free circulation of the water, from the position in which the conical shells retain it, is greatly promoted. This form also provides an extensive combustion chamber, wherein the gases may become thoroughly ignited, while the rapidly narrowing passage towards the flue, in both the vertical and horizontal direction, so progressively retards the gases in their passage to the outlet, that their combustion is perfected, and their heat, as far as possible, imparted to the boiler. There is no lodgment for refuse, ashes and dirt about the boiler, and all sediment within is naturally deposited at its lowest point, T, whence it is easily blown off. The advantage derived from setting the boiler without contact with the brick-work is great, for when, as is necessary with ordinary boilers, the brick-work and the boiler are brought in contact, any water from the top will settle at the point of contact, become decomposed, and very quickly weaken the boiler by oxidizing the iron. The "Society for the Prevention of Boiler Explosions," in England, report that 50 per cent of the explosions of stationary boilers are clearly traceable to this cause. Unequal expansion and contraction are also, doubtless, as much promoted in a boiler but half bricked in, as in a tubular or locomotive boiler with its varying diameters and position of shell and tubes; for the upper half, exposed to the atmosphere, while the lower part is subject to intense heat, must be unequally affected, and soon lead to the rapid destruction of the boiler.

The Portable Boiler.—This boiler, Figs. 9, 10 and 11, has the form throughout of a locomotive fire-box, with a double shell all over, and open at the back end, the space between the shells being about 3 in. at the bottom, 4 in. at the sides and front end, and 10 or 12 in. at the top. Within this fire-box shaped boiler is placed an exact counterpart of the Gerner stationary boiler. The feed-pipe to both the inner and outer boiler is shown at F F, and the connecting pipe at X. Apart from these two pipes there is no water or steam connection between the two boilers, and with these connections severed, the boilers become in fact two separate steam generators. The inner boiler is supported by a rod in its front end, resting within an expanded tube in the front of the outer boiler, and by two set screws S S, Fig. 11, which pass through lugs in the dome, on to a plate on the outside of the outer boiler. The open end of the outer boiler, after the inner boiler is placed in position, is closed by a cast-iron plate, which arrests the flames after their passage around and underneath the inner boiler, and diverts them into the uptake or chimney. A plate R is placed underneath the inner boiler near the back end, to reduce the size of the escape flue, and to compel the heat to strike the bottom of the boiler in the rear. The water-line in both boilers is the same, and the steam from both is conveyed into the steam reservoir B.

It is a well-known fact that the fire-box of a locomotive boiler is its most effective part, owing to the free development and maintenance of the flame in one mass, not divided by flues, thus illustrating the rule laid down by Sir Humphrey Davy, that "heat communicated by flame depends on its mass." This principle has been still further illustrated by the fact, that the efficiency and economy of many tubular boilers has been greatly increased by lengthening the fire-box and cutting down the length of the tubes. In view of these facts, it is claimed that the outer boiler, above described, furnishes very effective and desira-

Fig. 9

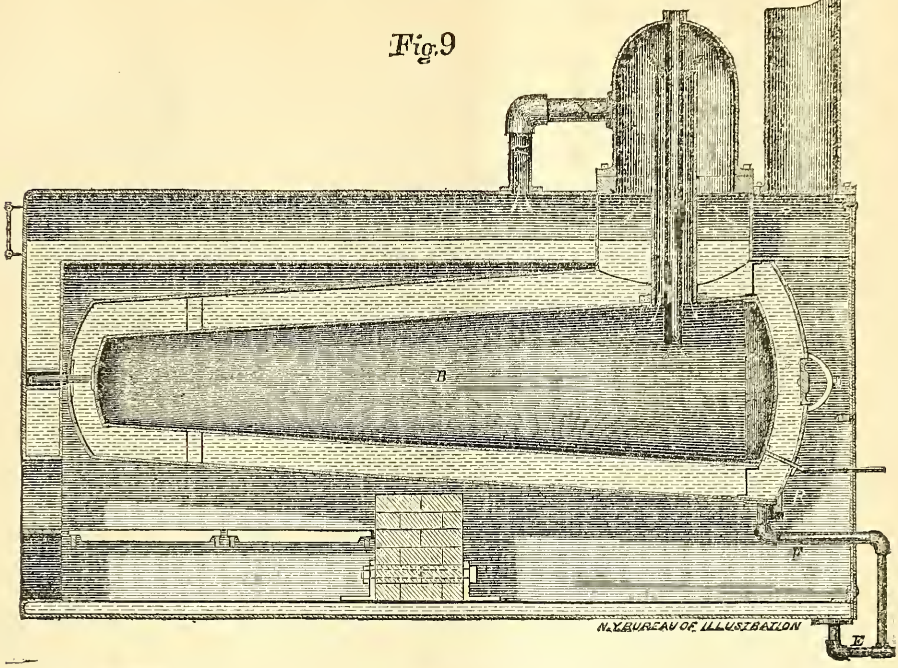

Fig. 11

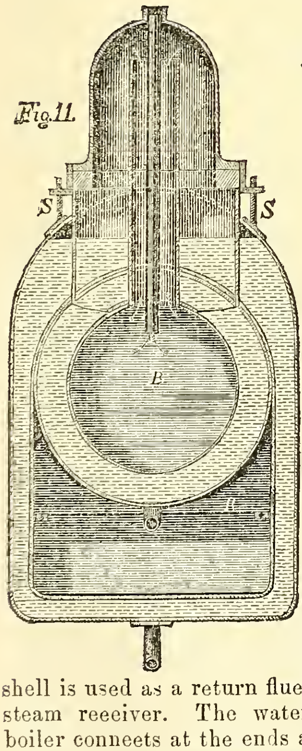

Fig. 10.

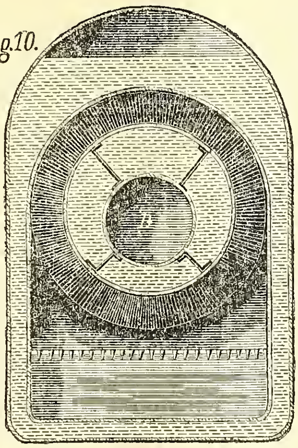
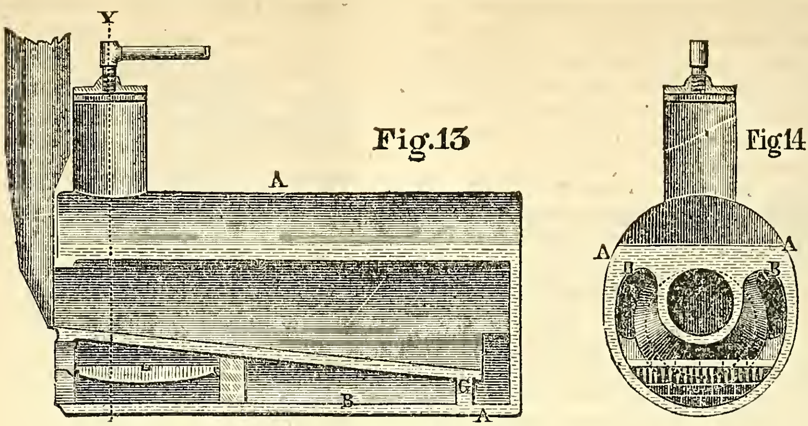


able surface for the generation of steam, without presenting any impediment for the free circulation of the water within, or lodgment of ashes or refuse without; and that the inner boiler adds the other advantages of the Gerner principle.

The Marine Boiler.—This boiler, Figs. 13 and 14, may be described as a single return conical flue boiler, forming a conical combustion chamber. Its peculiarity consists in its conical shaped flues and their annular water spaces.

The outer shell A is a plain cylinder, the inner shell B conforms to the shape of the outer shell (forming a space increasing from 4 to 6 in. between the two), to a height somewhat above the center of the boiler, from thence it turns inwardly, and dropping down connects with the outer shell of the double-shelled conical flue. This doubled shelled conical flue traverses the length of the boiler, its smaller end being over the grate bars, and the interior of its inner shell is used as a return flue to the uptake at the front of the boiler, instead of an interior steam receiver. The water space of from 4 to 6 in. between the shells of the outer boiler connects at the ends and on top with those of the doubled shelled flue, which are of the same width, and there is a further connection between the water bottom near its back end, and the water space around the conical flue at its largest end, by the



The Gerner Marine Boiler.

circulating pipe G. The fire-box or furnace portion of the boiler, it will be seen, is very extensive, wherein the flame is maintained in an undivided mass, and the heating surface on all sides presented to its action in a manner best calculated to obtain great efficiency. The gradually narrowing passage towards the opening into the return flue retards the gases of combustion until the greater amount of direct heat is utilized, and after entering the flue, they are still further retarded in their escape to the chimney by the tapering form of the flue, and their entire available heat imparted, as far as possible, to the plates containing thin sheets of water.

Rate of Evaporation.—The authority we have referred to gives, "from actual knowledge," the results of a trial of a Gerner stationary boiler, by the means adopted in the U. S. Navy experiments. The boiler is 10 ft. long, 2 ft. front, and 3 ft. rear diameter, with a grate surface of $4\frac{44}{100}$ sq. ft. The experiments show that the boiler is producing 500 lbs. of dry steam per hour for every 50 lbs. of coal consumed, after setting aside the fraction .65 of a lb. over 10 lbs. of steam produced by the consumption of a pound of anthracite. This margin of 6.5 per cent of the total production will cover many of the defects of unskillful firing. Assuming, then, that in practice the boiler will evaporate 500 lbs. of water per hour with a consumption of 50 lbs. of coal, and allowing 33 lbs. of water to be the fair standard of a horse-power, this boiler is capable of supplying 15 horse-power. The total heating surface being $83\frac{30}{100}$ sq. ft., and the results obtained being over 15 horse-power, shows $5\frac{1}{2}$ sq. ft. in these boilers to be sufficient to produce a horse-power, and illustrates the efficiency of the heating surface.

The test of a marine boiler (*i. e.*, built upon the same plan as one intended for a steam-vessel) now in operation at the New York and Erie R. R. General offices (Grand Opera House), New York, is given by the same authority. The boiler is 16 ft. long, $6\frac{1}{2}$ ft. in diameter, and has produced, according to the testimony of J. W. Brooks, Superintendent of Motive Power N. Y. and E. R. R., 110 horse-power, 3,300 lbs. water evaporated per hour, with an economical result of over 12 lbs. of water to 1 lb. of coal. The entire heating surface being but 400 sq. ft., gives less than 4 sq. ft. to a horse-power.

This result may be better appreciated by taking in comparison a tubular boiler, say $23\frac{1}{2}$ ft. long by 6 ft. in diameter, containing with its tubes a total heating surface of 1,139 sq. ft. Such a boiler, by allowing the ordinary standard of 15 sq. ft. to a horse-power, would be estimated at 75 horse-power, and its steady economical result could hardly be relied upon at over $6\frac{1}{2}$ to 7 pounds water to 1 of coal, with no assurance whatever of the dryness of its steam.

There is no doubt as to the comparative inefficiency of heating surfaces made up of small flues. Various authorities have been quoted in this connection, among others Armstrong (revised by Bourne), who says that "the present construction of the multitubular boiler, as it is called, may be truly stated as a disgrace to the science of this age of progress." C. Wye Williams says: "Heat, communicated by flame, must depend on its mass;" also that "the tubular system is chemically, mechanically, and practically a destroyer of ignition and the sustained existence of flame." Again he says: "The result of the adoption of the multitubular system has been a less perfect combustion, a larger development of opaque smoke, a greater waste of fuel and heat, and a more dangerous application of it."

Various recent experiments within our own knowledge appear to confirm these views. In one small locomotive boiler, for instance, the flues were almost entirely abandoned, and the fire-box was extended nearly the whole length of the boiler with good results. Exact experiments, however, have not been made in this case. The following considerations, at least, will be admitted by all experts: fire-box surfaces are vastly more efficient than flue surfaces. In the multitubular boiler, the flame entering the small tubes is extinguished, combustion of the gases ceases, and a very large proportion of the otherwise available heat pases off in smoke and unconsumed gases, and is lost; free circulation of water is obviously impeded by the multitude of small tubes, and the small inctrstices between them provide a very ready means for the retention of impurities in the water, and consequent incrustation; and, finally, the mechanical difficulty of keeping the tubes tight, in their varing expansions and contractions, is an expensive and dangerous experience to almost all who have used them.

The claim of *economy* made for the Gerner boiler appears, therefore, to be well founded in theory as well as in practice. The *safety* of the cylindrical form, as compared with flat sides, is obvious. The other advantages claimed have been referred to in detail, with the descriptions of the various forms of the boiler. We may add that these boilers are guaranteed for a rate of vaporization in accordance with the results of the experiments above stated.

SAFETY CAR TRUCKS.—Mr. Morris, of the Housatonic Railway, has devised an improvement for relieving the effects of a broken car wheel or rail. He attaches to the truck frame, just inside of the wheels, two stout sled runners, made of heavy plank shod with metal or entirely of metal. In case of running off the track, these runners receive at once the weight of the car, and prevent all but a slight sinking of the wheels. They act as brakes to check the speed and also prevent lateral motion of the car.

COMBUSTION UNDER PRESSURE.

From "Engineering."

We propose to explain briefly what we believe to be the theory of Mr. Bessemer's system of high-pressure furnaces, and show why the fact of the combustion taking place under pressure should cause the intensity of the heat produced to be increased. Fifteen or sixteen years ago, before the question had been settled by the experiments of Regnault, it was considered by many investigators, who either disbelieved or did not perfectly comprehend the dynamical theory of heat, that the specific heat of air and other gases was decreased by an increase in the pressure under which they were confined. We should not have referred to this fact here, but that some recent writers, arguing falsely from the experiments made by Clements and Desormes early in the present century, have endorsed this opinion, and stated that the specific heat of gases decreased as the square root of the pressure to which they were exposed. According to these theorists, the increase of temperature obtained by Mr. Bessemer's high pressure system would be simply due to the fact that the gases generated by combustion being under pressure, had a less specific heat than those escaping from an ordinary furnace fire, and that consequently a given quantity of heat was capable of raising them to a higher temperature than could be obtained under ordinary circumstances. The admirable experiments of Regnault, however, described by him in the "Comptes Rendus" for 1853, conclusively proved that the specific heat of air was sensibly constant at all pressures and temperatures at which it was tested, and the explanation we have just mentioned is therefore an untenable one. We shall now proceed to state what we believe to be the true explanation of the results obtained by Mr. Bessemer, these results being, we consider, fully accounted for by the dynamical theory of heat.

It was long ago shown by Poisson and Laplace that the quantity of heat required to raise the temperature of a given weight of any gas, a certain number of degrees, is less if that gas was maintained at a constant volume, than if it is allowed to expand freely during the heating process. In other words, the specific heat of a gas maintained at a constant volume is less than that of the same gas maintained at a constant pressure, the difference in the two specific heats under the two circumstances being due to the heat absorbed in performing the work of expansion. In the case of air the two specific heats have been ascertained to be .169 and .238 respectively (that of water being denoted by 1), and it thus appears that a pound of air in expanding to the extent due to a rise of temperature of 1°, absorbs, or renders latent, .238—.169 = .069 of a unit of heat. It is to this fact that the heating of air which takes place under compression is due, for when a quantity of air is reduced in bulk, the heat which had been previously employed in maintaining it in an expanded state becomes re-converted into sensible heat, and the temperature of the air is raised accordingly. It will thus be seen that the compression of the air does not increase the quantity of heat contained in it, but merely renders sensible a portion which was previously latent, and it follows, therefore, that a certain weight of air or gases containing a given quantity of heat will have a higher temperature if compressed than if maintained at ordinary atmospheric pressure.

In Mr. Bessemer's high-pressure furnaces the gaseous products of combustion are, it is true, not allowed to expand and then heated by compression, but they are prevented from expanding as they would do in an ordinary furnace, and, as far as the results go, the effect is the same. In other words, in a high-pressure furnace working at a pressure of, say, two atmospheres, the temperature of the gaseous products of combustion is the same as if they had been allowed to expand under ordinary atmospheric pressure, and then suddenly compressed until the pressure became doubled. Now it can be shown by reasoning founded on the data we have given, that what is known as the *absolute* temperature — or the temperature in degrees Fahrenheit + 461.2°—of any given quantity of air will, if that air be compressed, vary as the .29th power* of its pressure above a vacuum ; or, in other words, if T_1 = absolute temperature of a certain quantity of air under a pressure P_1, its temperature, T_2, under another pressure, P_2, will equal $T_1 \times \left(\frac{P_2}{P_1}\right)^{.29}$. If now we assume, as we probably may do without any sensible error, that this formula for air is applicable to the gaseous products of combustion obtained in a high-pressure furnace, we shall be in a position to calculate the increase of temperature due to the adoption of the high-pressure system in any particular case. Perhaps an example or two may render this clearer.

Let us suppose, for instance, the case of a furnace in which the proportions of carbonic acid and carbonic oxide produced by the combustion of the fuel are as one to four, and let this furnace be worked, in the first instance, under ordinary atmospheric pressure. Now, we showed in the early part of the article, in our number for the 17th ult., to which we have already referred, that when carbon is supplied with just sufficient air for combustion, and is burnt into carbonic acid, the highest temperature theoretically obtainable is about 4,500°, while if it is burnt into carbonic oxide, the temperature will be about 2,250° only. In the case we are now considering, therefore, supposing that there is no loss of heat from radiation or the admission of excess of air, etc., the most intense heat attainable will be $\frac{(2,250 \times 4)+4,500}{5} = 2,700°$ above the temperature of the air and fuel introduced into the furnace. If, now, the temperature at which the materials are introduced be taken as 60°, the temperature of the products of combustion under the above circumstances will be 2,760°, and their *absolute* temperature 2,760 + 461.2 = 3,221.2°. Let us next suppose that the furnace is worked at a pressure of 15 lbs. per sq. in. above the atmosphere, or, say, at a pressure of two atmospheres, the products of combustion being the same as before. In this case the *absolute* temperature of the products instead of being 3,221.2°, will be $3,221.2 \times 2^{.29} = 3,221.2 \times 1.222 = 3,936.3°$, and their temperature expressed in the ordinary way will be 3,936.3—461.2 = 3,475.1, or, say, 3,475°, being a temperature 715° higher than that obtained in a furnace worked at atmospheric pressure. In the same way we should expect to find that if the pressure under which the furnace is worked is increased to three atmospheres, the temperature of the products of combustion will rise to $(3,221.2 \times 3^{.29}) - 461.2 = (3,221 \times 1.375) - 461.2 = 3,967.9°$, or, say, 3,968°, a temperature more than 1,200° in excess of that obtainable under ordinary circumstances.

It will, of course, be understood that the temperatures above given are merely rela-

* The .29th power of any number may be readily obtained by the use of a table of logarithms.

tive, being illustrative of the effects due to the high-pressure system of working as compared with what we may call, for distinction, the ordinary low-pressure system. In practice the actual temperatures obtained will depend not only upon the pressure used, but also, for the reasons we have already explained in our former article, upon the completeness of the conversion of the carbon of the fuel into carbonic acid, and upon the manner in which the supply of air is adjusted, as well as upon the means adopted to prevent loss of heat. Mr. Bessemer is, we understand, about to try a series of experiments on a furnace worked at various pressures, and we look forward with much interest to the results of these experiments, which we shall be glad to know agree with the theory we have advanced.

Transmission of Power by Wire Ropes.—There are, at Moulins Galant, near Corbeil, 22 miles south of Paris, some important paper mills belonging to MM. Darblay and Company. One of these mills is worked by an hydraulic wheel of about 30 horse-power. But the power of this wheel not being sufficient all the year round, it was necessary to provide a supplementary power, which has been obtained from another fall on the same river, 770 yards up the valley. This fall, of about 40 or 45 horse-power, was formerly, and is even now, used for working a flour mill, which has been taken on lease by M. Darblay. The connection between the flour mill and the paper mill has been made with a telodynamic* wire. This system of transmission consists of an iron endless wire supported by pulleys, and running at a very great speed. It is thus possible to transmit a large power through a very thin wire, and this system is now extensively used in France, especially in the eastern districts. The Moulins Galant wire is worth notice, because, besides its great length, the axles of the driving and driven pulleys are neither parallel nor situated at the same level. The angle between these axles is 8 deg. 10 min., and the driving axle is 14 ft. 1 in. above the other; both are, of course, horizontal. The wire has been arranged in a polygonal line, and at each summit of this polygonal line there are two pulleys, bearing the driving and the driven wire. It was necessary to give to the axles of these pulleys such an inclination that the plan of the pulley should include the tangents to the two adjoining curves of the wire by each side of the pulley. The shape of these curves, and the inclination of their tangent, had accordingly to be calculated with the greatest care; and the pulleys had afterwards to be accurately arranged in the calculated situation. Any mistake in these calculations would produce a great waste of power, and sometimes would enable the wire to get out of the grooves of the pulleys. All this plant has been successfully arranged by MM. Callon and Vigreux, civil engineers, and it has worked quite well for nearly eight months. The diameter of the rope is $\frac{1}{2}$ in., it weighs 9 lbs. per yard, and it consists of 48 iron wires $\frac{1}{24}$ in. diameter, and of a central hemp strand of about $\frac{1}{4}$ in. diameter. The speed of the rope is 61 ft. 9 in. per minute, and the calculated strain is 666 lbs. on the driving, and 313 lbs. on the driven wire. The diameter of the driving and driven pulleys is 8 ft., and they have an angular speed of 150 revolutions per minute. The hydraulic wheel running only $3\frac{1}{2}$ revolutions per minute, the proper speed is given to the driving pulley through two intermediate wrought-iron shafts, supplied with cast-iron spur-wheels. The wire is supported by seven intermediate pulleys, 6 ft. 6 in. diameter, and there is an average span of 246 ft. between these pulleys. There are some masonry piers, 10 ft. to 20 ft. high, carrying these pulleys, and supplied with wrought-iron ladders for oiling the journals. The average deflection of the wire between the pulleys is 10 ft. for the driven and 5 ft. for the driving wire. This latter runs very near the ground in some places through the meadows. The inclination on the horizontal of the shafts of the pulleys is 4 deg. 8 min. for the driven, and 8 deg. 28 min. for the driving wire. It is also necessary to calculate very accurately the total length of the rope; upon the length depends the tension; with a too great length the wire could be allowed to slip in spite of the leather lining of the grooves of the pulleys; with too short a wire the friction would be uselessly increased; in both cases the wire would be liable to fall down the pulleys. This dangerous accident happened once at Moulins Galant, the wire being pulled by a hay cart crossing under it, but nobody was injured. The calculated slack of the wire is about 20 ft., and this length has been ascertained to answer quite well. There is

* From the Greek τηλε far, and δυναμις power.

a telegraphic connection between the two mills in order to stop the wheel when there is some accident to the paper mill. The flour mill is of course kept at work when there is in the river a sufficient flow of water, and when all the requirements of the paper mill are performed. The waste of power by friction is about one-sixth of the total power. The wire is without any connection with the paper engine of the paper mill, which is worked by a small steam engine.

It must be remembered that when such ropes are worked in connection with a steam engine, this latter wants a very powerful quickly acting governor, in order to prevent the overrunning of the engine, should the wire suddenly break down. Such an accident happened, some years ago, in a cotton-spinning works in Alsace, and a large steam engine was entirely destroyed.—*Cor. The Engineer.*

COIGNET'S ARTIFICIAL STONE.

From "Engineering."

For about twelve years the "Béton aggloméré" of M. F. Coignet has been employed in France, at first sparingly, and with hesitation, but of late so largely and with so much confidence, that many of the large works in and near Paris have been constructed for the most part, or entirely, with this material.

So early as 1850, M. Coignet had experimented further than his predecessors Fleuret (1800) and Lebrun (1829), but the conglomerate he then produced was unsatisfactory. In the commencement he employed a crude mixture of coal cinder with lime, and subsequently he substituted sand for the former ingredient, and mixed it with powdered lime, moistening both together instead of wetting the lime as he at first done. The second process to which he arrived, after modification and a long series of experiments with materials from different districts, and under varying circumstances, to ascertain the best proportions, is the system which has now grown into such a vast industry, and which bears his name.

The béton Coignet is a mixture of a large proportion of sand with a small proportion of lime, to which is added a percentage of cement varying with the amount of hardness or the rapidity of setting required. Only a very small quantity of water is employed to moisten the lime and sand. Thus tempered the mass is reduced, in a grinding mill, to a stiff paste, and is introduced into moulds of any desired form, being then subjected to the action of repeated and heavy blows. By this means it is thoroughly agglomerated, and the mould being almost immediately removed, the béton, shaped to the desired figure, shortly becomes set, and acquires the hardness of stone.

The material thus mixed and compressed under the hammer, when placed in the mould, receives a weight, strength, and density which renders it a thoroughly trust-worthy building material. On the average 1.31 bushels of component parts, sand, lime and cement, make a cubic foot of béton which will weigh about 140 lbs., and offer a resistance of some $2\frac{1}{2}$ tons per square inch, while ordinary mortar, formed of the same constituents, will exhibit very insignificant powers of resistance. The difference arises principally from the difference in manipulation; in mixing mortar an excess of water is always used, which is distributed throughout the mass, and separates the particles of lime and sand, retarding the setting, and when after a time the water evaporates, it leaves the mortar more or less porous.

Theoretically, the Coignet process fills all the necessary conditions, and produces a perfect béton, the sand and lime being moistened with a minimum of water, and mingled as intimately as possible. Besides the thorough cohesion of the particles induced by the mixing and compression, the small quantity of water used makes the setting more rapid and more uniform.

In all cases the lime used should be hydraulic, in fine powder, and well screened, to free it from lumps; for if there are any lumps admitted into the béton they swell when the mixture is diluted, and weaken the material.

The cements used are always, if possible, heavy and slow setting. The quantity used is proportioned to the rapidity of setting required, and the hardness of stone which it is sought to obtain. For the third ingredient, river sand, mingled with small pebbles, is the best. If the pebbles are large, the concrete produced is rough and unsightly; if it is too fine, it retards the setting, and reduces the hardness. Pit sand will make very good work, but to produce a stone so good as that formed on a base of river sand, the proportions of cement and lime have to be increased. Very fine sands like those of the Landes, require very careful mixing and a prolonged compression in the mould to produce a first-class béton.

The ingredients are measured into a mixing mill in barrows, and during the process small quantities of water are gradually added as the mixing proceeds, until the béton becomes in the necessary condition; the more completely this part of the work is done the more rapid will be the setting, and the harder will the stone become.

The ordinary form of grinding mill employed consists of an iron cistern, the bottom of which is perforated, and in the center of which revolves a vertical shaft, armed with a number of helical knives, and carrying beneath it a cycloidal arm, which in each revolution discharges a part of the paste. A penstock covering the outlet regulates the discharge of the béton. The material thus obtained from the mill is in a firm but plastic state, and it is thrown into a mould, in thin layers, and each layer, as it is laid in, is beaten and compressed by the regular and even blow of a sixteen pound hammer. In order to secure a perfect adhesion and union of the different layers of material, especially when fine sand is used, it is generally the custom to cross cut the surface of the layer in order that the superincumbent thickness may be thoroughly united to it.

There are two kinds of moulding to which the Coignet béton is applied, the first being used when the material is employed *en masse* in place, the second when it is moulded in blocks to be subsequently employed. The moulds which are intended to be used in place are composed of close boarding kept in place by means of cross bracing. This mould carries the ornaments which are destined to appear upon the face of the structure after completion. In the second class of work all kinds of ornament can be produced from cornices to statuary.

Of late years the application of the Coignet béton has been equally extensive and varied. In Egypt, where it has been employed on a vast scale, light-houses have been reared out of the almost impalpable sands of the Isthmus of Suez. In Paris, some 40 miles of sewers have been constructed of the same material; and arches of the basement buildings of the Exhibition of 1867, saw mills at Aubervilliers, the numerous cellers of many private houses, entire buildings of five and six stories in height, railway bridges at Sainte Colombe, on the Paris, Lyons, and Mediterranean line, a church at Vérinet, and above all the large works connected with the new Paris water supply, and some examples of which we illustrate on another page.

The exact proportion of materials employed on works of different classes, and with sand and lime produced from different districts, will be interesting. Thus the work about the Exhibition of 1867 was formed of a mixture by bulk of 5 of sand, 1 of lime, and $\frac{1}{4}$ of cement. The same proportion holds good for the sewers, and the rapidity of setting is as great, that the centering can be struck within ten hours after the béton is got in place, and the sewers can be put into service in four or five days after their completion. Arches, of which the rise is one-tenth of the span, are generally made with a mixture of 5 of sand to 1 of lime, and $\frac{1}{2}$ of cement in bulk.

The church at Vérinet is one of the most interesting of the monolithic structures, and was constructed of sand from pits at Vérinet. The mixture was 5 of sand to 1 of lime and $\frac{1}{4}$ of cement. In the saw mill of Aubervilliers, the arches are 27 ft. 10 in. in span and $13\frac{3}{4}$ ft. thick at the crown, the proportions are also 5, and 1, and $\frac{1}{2}$ of cement. One of the most generally useful applications of this material is in the construction of the basements of houses. In the ordinary form of construction, stone piers, supporting rubble masonary arches, are employed, involving numberless joints, and causing an absence of perfect uniformity. From this cause numerous settlements ensue, which are avoided by the use of the homogeneous béton; for the whole sub-structure can be made in one single block, over which the superincumbent load is equally distributed, and a uniform pressure upon the foundation is obtained. One house, in the Rue de Miromesnil, is constructed entirely of béton, and it contains two staircases, the one formed in the usual way, with a number of moulded blocks, the other a spiral staircase, from basement to garret—a monolith.

Aqueducts are now being constructed from this stone upon the works for the supply of Paris with water from the Vanne. Already a part of the city draws its supply from the Dhuys, but the second portion of the system is not yet complete. The distance of Paris from the source of the Vanne is more than 94 miles, and in its course to the city the line has to traverse a series of valleys and ravines, to cross rivers, roads and railways, and the numerous requirements of the works have involved the formation of extensive bridges, aqueducts, syphons, and tunnels. An immense reservoir will be completed close to the park of Montsouris, and a long aqueduct upon arches will be made almost close to the old Roman aqueduct of Arcueil. But the heaviest works upon the undertaking are those crossing the valley of Fontainebleau for a distance of more than twenty-five miles between the river Loing and the river Essones. This length almost entirely, without building materials, would have involved very costly works if masonry had been employed, and the engineer-in-chief, M. Belgrand, has therefore availed himself of the Coignet process, and utilizing the vast masses of sand that lay ready to his hand, has formed the work of béton. Not only have the aqueducts been constructed of this material, but the tunnels also to the extent of several miles, about 6 ft. 6 in. in diameter and 8⅝ in. thick, and these were all formed with the same success that has attended the application of the system to the sewers of Paris, the centres having been withdrawn almost immediately after the béton had been rammed into place. The aqueducts crossing the valley are supported upon arches, extremely light, and rising to a maximum height of 50 ft. from the ground. The openings are about 42 ft. 6 in., and the thickness at the crown 15¾ in. The success which attended the application of this material in the construction of the narrow openings supporting the aqueduct, induced the engineer to extend its use to those wider arches spanning rivers, roads, and railways, and, a series of experiments having proved highly successful, monolithic structures, of 98 ft. 6 in. and 115 ft. 9 in. openings, and with one-sixth rise, were rapidly formed.

It will thus be seen that while we have refrained from experimenting (with one exception) in this method of construction, French engineers have advanced to recognize its value, and to employ it largely for a variety of work, having tested its reliability by a series of exhaustive trials. The single exception to which we refer is the concrete bridge constructed by Mr. Fowler across the Metropolitan Railway at Kensington, but even that experiment was scarcely analogous, for the material employed was simyly concrete, mixed with cement it is true, but mixed in the ordinary way, and thrown into the mould instead of being carefully set in the layers and well combined, as in the Coignet process. But the extensive adoption of concrete structures in France will probably be followed by an equally extended adoption of the system here.

BLAST-FURNACE BLOWING-ENGINES.

Translated from a paper read by Mr. SCHMAHEL, before the Upper Silesian Society of Engineers.

The Upper Silesian Society of Engineers had, in a former meeting, proposed the following questions:

Which blowing-engines are preferable, those with upright, or those with horizontal cylinders? and what are the reasons why the one or the other of these constructions is preferable? Is it advantageous to use two or more small blowing-engines in the place of a single large one?

These questions may be answered in the following manner: Horizontal blowing-engines are mostly high-pressure engines. They are not expensive, easily accessible, simple in their arrangement, and can be safely founded on almost any kind of ground. The clearance in the air-cylinders is very small. On the other hand they do not allow of a very long stroke; their piston-rods are liable to be bent, and the pistons as well as the piston-rods are worn-out unevenly, thereby causing loses of blast from leakage. They require a large surface of ground, and use a considerable quantity of lubricating materials.

Vertical blowing-engines may be constructed with beam and fly-wheel, or direct acting without fly-wheel. The former are preferable.

When compared to the horizontal engines, the vertical engines with fly-wheel have the following advantages:

1. They require less room.
2. They can be constructed with a longer stroke, which tends to diminish the loss of blast.
3. The wear of the pistons, cylinders, and stuffing-boxes is smaller.
4. The piston-rods can be guided in a more perfect manner, and thus be prevented from bending.

These engines are, however, much more expensive than those with horizontal cylinders, because they have to have a beam, and a greater number and more complicated connecting parts. They also require stronger foundations for the cylinders as well as for the stands which support the beam.

Wherever the cost was considered an important point, and where sufficient room was available, the horizontal engines have formerly been generally preferred. Of late, however, new blowing-engines for blast-furnaces are mostly constructed with beam, fly-wheel and upright cylinders. Vertical and direct acting blowing-engines, without fly-wheel, do not work economically when two or more such engines have to work together, as is mostly the case. For it is then to be feared that from an accidental stoppage of one of them, the pressure of the blast on the pistons of the others would be so suddenly diminished that too violent a motion might take place which would produce the breakage of the cylinder-covers, of the pistons, of the piston-rods, of the counter-balance, or of other parts of the mechanism. To prevent such accidents the cylinders must be made longer than the stroke. This causes a considerable waste in clearances, loss of blast, and a diminution of the working effect of the engine.

I had, recently, the opportunity of inspecting a great number of blowing-engines at different German iron works.

The horizontal engines I saw had blowing eylinders of 5 to 8 ft. in diameter, and 4 to 8 ft. stroke, working at a speed of 72 to 150 ft. per minute. On all these engines, with but a few exceptions, I noticed the bending of the piston-rods. Amongst the larger engines of modern construction, which I inspected, but two were free from this defect. They had hollow cast-iron piston-rods of 9 to 10 in. diameter, resting on slides 15 in. wide and 18 in. long. The pistons were made of iron-plate. The engines made 10 to 12 revolutions per minute, which number could however be increased to 20 without any trouble or danger.

A wear of the lower part of the piston-rods was not perceptible, owing to the large surface of the slides. All the vertical engines I met with were beam-engines with fly-wheel. The smallest cylinder of this kind of engines had $5\frac{1}{2}$, the largest 10 ft. diameter. The shortest stroke was $7\frac{3}{4}$, the longest stroke 9 ft. The speed varied from 144 to 288 ft. per minute. It is seen from these numbers, when compared with those mentioned before, that the vertical beam-engines can be built of larger size and more powerful and effective than those with horizontal cylinders.

As to the question whether two or more smaller engines are preferable to a single large one, it may be said that smaller engines are preferable when more than one blast-furnace has to be worked. The running expenses are more considerable, it is true. But the losses of time and work, caused by stoppage for repairs of the engine, will amount to a much higher sum, when two or more blast-furnaces are dependent on a single blowing-engine. S.

IRON AND STEEL NOTES.

Fettling or Lining Puddling Furnaces.—In the ordinary method of fettling or lining the beds and sides of puddling furnaces oxide of iron or a compound consisting mainly of oxide of iron is employed for that purpose. An invention patented by Mr. W. M. Williams, of Sheffield, consists in lining puddling furnaces with crude or prepared oxide of manganese or manganese ore, either as the chief ingredient of the fettling or as an addition to the oxide of iron or other material, which is employed. In using crude or native oxide of manganese or manganese ore without admixture with other solid, an ore is used which when pulverized and moistened will form a plastic or pasty mass, and which when heated will harden and adhere firmly to the sides and bottom of the puddling furnace. For this purpose the cheap oxides containing a considerable proportion of iron are best suited, provided they do not also contain other impurities, such as sulphur and phosphorus which would injure the iron in the furnace. When an ore or prepared oxide is used which does not harden sufficiently, after being rendered plastic by water alone, it is mixed with a sufficient quantity of finely powdered and moistened hematite or other suitable material to give it the property of hardening and adhering when heated in the furnace.

The proportions in which oxide of manganese and oxide of iron should be mixed in order to make the fettling according to this invention, vary with the nature of the cast or pig iron to be puddled. With pig iron of ordinary quality about half a hundred weight of oxide of manganese mixed with the requisite quantity of oxide of iron for the fettling of the furnace is sufficient for a charge of four to five hundred weight of pig iron. When the pig iron itself is rich in manganese a less proportion is necessary in the fettling. When the pig iron contains a large quantity of silicon and little manganese, more oxid of manganese is required in the fettling than is required with pig iron containing much oxide of manganese and little silicon. Where practicable, the inventor prefers to introduce the pig iron into the puddling furnace in a melted state; when this is done and the fettling containing oxide of manganese is laid on the bottom and lower part of the sides of the furnace, the charge gets the full benefit of the evolution of oxygen, which takes place when the oxide of manganese is heated. By the use of oxide of manganese, as described, the puddling process is expedited, and the quality of the iron or steel produced is improved. The heated iron or steel during the puddling process decomposes the oxide of manganese, causing an evolution of oxygen, which rising through the molten iron or steel rapidly oxidizes the oxidizable materials contained in the metal. A portion of the reduced manganese enters into alloy with the iron or steel and effects the improvement in the quality of the metal which is well known to result from the use of manganese in the manufacture of iron or steel.

When oxide of manganese is mixed directly with the charge for fluxing, as has been proposed, a portion is liable to become mechanically distributed through the mass of iron ot steel in the state of an infusible powder, consisting of manganese in a low state of oxidation, and injures the mechanical properties of the metal. But when oxide of manganese is used in the fettling of the puddling furnace, according to this invention, it is gradually decomposed as the carbon and silicon of the pig iron or steel are presented to it by the stirring of the puddler, and the manganese enters the charge in a fused state either as reduced metal or as silicate.

Very little of the manganese which enters the iron or steel during the puddling process remains in the finished metal, most of the manganese separating during the finishing of the metal in the form of silicate of manganese, carrying with it other impurities, such as phosphorus and sulphur. The silicate of manganese separates from the metal more readily than silicate of iron, and is found in considerable quantity in the cinder and hammer slag. The cinder and hammer slag are therefore more valuable than ordinary cinder or hammer slag for the making of cinder iron in consequence of their richness in manganese. Although the fluxing property of oxide of manganese, either alone or mixed with oxide of iron, renders the addition of any other material to the fettling unnecessary when pig iron or steel of the ordinary qualities are puddled, yet when pig iron or steel of such quality as renders the use of alkaline fluxes desirable is about to be puddled, common salt or carbonate or nitrate of soda may be added to the oxide of manganese. A quantity of the soda salt equal to about one-fourth the weight of the oxide of manganese is generally sufficient.—*Mechanics Magazine.*

Mons. C. Schinz on Messrs. Ponsard and Boyenval's Improvements in the Manufacture of Iron.—To aim at obtaining wrought iron directly from the ores appears to be, at first sight, the most legitimate course which the inventions on the subject of iron production could take. Yet, as a matter of experience, it is plain that unless we have to deal with exceptionally rich ores, the proceeding is far from being an economical one. This becomes more apparent when we take into consideration the measures which from time to time, and up to the present day, have been adopted or proposed in carrying out this scheme. Neither Clay, in 1837, nor his successors, Renton, Chanot, Yates, Gurit, Rager, Siemens, and recently Ponsard and F. F. Boyenval, have succeeded in solving the problem satisfactorily. With or without the use of the blast-furnace, the oxide or peroxide of iron has first to be reduced in the ores. We have on a former occasion given a lengthy description of M. Schinz's labors on the subject of blast furnaces, and must refer our readers to those columns for the better understanding of M. Schinz's position regarding the subject before us. M Ponsard himself has lately ("Comptes Rendus," p. 177) laid his views before the Academy at Paris. He starts from the fact that the fuel used in the blast-furnace is excessive, and far beyond what is required "theoretically" for the reduction of the ores, the carbonizing of the iron, and the smelting of the pile. He proposes a separation of the chemically acting carbon from that which is consumed for heating purposes, and goes on to assert that but 1,000 kilogrammes of coal, instead of 3,000, as ordinarily used per ton, are needed according to his plan. M. Schinz says that Ponsard and Boyenval's patent is not much more than the ordinary test process of the laboratory on a larger scale; the only difference being that, whereas in the ordinary trials a surplus of carbon and scoriæ is added, he, M. Ponsard, used merely the exact quantity requisite for carbonising and smelting. This process, however, is the same as that going on in the hearth of the blast-furnace when the ores arrive there unreduced. The peroxide of iron (or sometimes the oxide) is reduced by the contact with solid carbon. This reduction, however, is not confined to the oxides of iron alone; other substances contained in the scoriæ are effected in the same manner and yielding sulphur, phosphorus, silicium, &c., which are by no means desirable companions for the produced article. In the blast-furnace, hot air and an insufficient supply of scoriæ generally produce this bad effect partly; while Ponsard's apparatus is so arranged as to have it throughout. The resulting inferior material will have to be refined, and, in that case, the inventors can hardly claim to have saved anything by their so called direct production.—*The Engineer.*

Lurmann's Blast Furnace.—A considerable number of German ironmasters have, during the last two years, applied to their furnaces the system of Mr. Lürmann, the manager of the Georg-Marien Mining and Iron Company, of Osnabrück, Prussia, the improvement consisting in closing the front of the hearth, thereby dispensing with the dam stone, tymp, &c. A scoria outlet is set in the closed breast at a distance of about 6 in. below the tuyeres, and through this outlet the slag runs off regularly and constantly. The tapping hole is placed where the heat is greatest.

This arrangement has been successfully worked for six months or more at the Old Park Ironworks, Shropshire, and more than one of our leading ironmasters have expressed their intention of adopting it. Its advantages are thus enumerated:

1. The slag discharges itself through the scoria outlet at about the same level, therefore there are no vacillations of the slag in the hearth, and the corroding of the wall is diminished.

2. As there is no fore-hearth, there are of course no repairs, and no breaking up of the scoria-crust in the same. This is equal, as shown above, to a saving of at least 20 days per year. Suppose a large furnace produces 40 tons per day, the same will yield at least 800 tons per year more, if built on Mr. Lürmann's principle, than if it were of the ordinaay construction.

3. As there are no interruptions, the furnace does not cool. It works more regular, as the heat in the furnace is always the same.

4. The doing away with the dam and the fore-hearth allows the removal of the tapping-hole from the former into the wall of the hearth. The opening of the tapping-hole is then easy, as it is close to the greatest heat.

5. The completely closed earth allows a con-

siderable increase of the pressure of the blast, because a throwing out of materials has become impossible.

6. The increase of the pressure is always of great importance, but especially where pit coal, anthracite, &c., are used; and where the layers are compact. The number of charges can be greater, effecting a corresponding increase of produce.

7. The augmentation in the number of tuyeres, and the equal distribution of them, made feasible by the doing away with the forepart of the hearth, allow a better and equal distribution of the blast in the hearth; the furnace therefore works better, and a greater quantity of ore is smelted, provided there is sufficient blast.

8. The number of hands may be lessened, as the operations are few and easy; the same need not be of great skill and experience. No fire clay and other refractory materials for the repairs, and less tools are wanted. It may be mentioned that formerly the smelters of Georg-Marien-Hütte, when working, were almost stripped; now they are always in full working dress.—*The Engineer*.

The Cambria Iron Works.—The largest iron works in the country are the Cambria Works, at Johnstown, Pa. They cover an area of about five acres, run night and day, and give employment to about 3,000 hands. They contain 42 double furnaces, over each of which is a steam boiler connected with the engine. The engine is a vertical one of 350 horse-power; its fly-wheel is $30\frac{1}{2}$ ft. in diameter, and weighs 56 tons. The capacity of the works is 1,400 tons of railroad iron per week. Last year they turned out 76,000 tons, and this year expect to produce 82,000.—*Am. Artizan.*

The engine referred to is that of the new puddle train, a three high train 5 rolls long, with two squeezers. There are besides, another puddle train, two rail trains and various small trains, each with its engine. The Bessemer Steel Works of the Company, adjoining the iron works, and capable of producing 50 tons of ingots per day, are also nearly completed.—Ed. V. N. M

Steel Rails and their use in America.—We quote the following from a comprehensive article in the New York "Tribune": The report of the exhaustive and important discussion held last year by the Institution of Civil Engineers in England, sums up the case in these words: "There can be no doubt as to the expediency of employing steel rails, even on railways where the traffic is light; but, of course, the heavier the traffic the greater will be the economy of substituting steel for iron."

In view of this forcible verdict in favor of steel rails, it becomes a matter of great public interest to know to what extent these rails are being laid in the United States. The report on railroads of the State Engineer and Surveyor of New York, prepared by S. H. Sweet, Deputy, and copied from the advance sheets, into "Van Nostrand's Eclectic Engineering Magazine" for last June, says: "It is estimated that from 40,000 to 50,000 tons of steel rails are in use on our various railways." Careful researches, made in this city during the past week, warrant the use of much more encouraging figures, and authorize the assertion that by the end of the year 1869 there will be laid in the United States, in round numbers, 110,000 *tons of steel rails*, equal to 1,100 miles of steel road; and of this amount about 36,000 tons, equal to 360 miles, will be laid during the present season! These rails are in use on more than 50 different roads, and are partly of American, principally of English, and to a very small extent, of Prussian manufacture.

Four large steel works for making rails have already been established in this country, and a fifth is nearly completed. John A. Griswold & Co., proprietors of the Bessemer Steel Works of Troy, N. Y., made about 2,000 tons of steel rails, half of them for the Erie railroad, prior to the burning of their works in October, 1868. None of these rails have broken, and official certificates testify that they are equal to the best foreign rails. The new works, now nearly completed will enable the proprietors to produce steel rails at the rate of 15,000 to 20,000 tons per year. The Pennsylvania Steel Works, at Harrisburg, are now, and have been for some time producing steel rails at the rate of 12,000 tons annually. These are mostly laid on the Pennsylvania Railroad, and the official reports show them to be equal to the best foreign rails. The yearly capacity of the works is 20,000 tons. The Cleveland Rolling Mill Company are producing steel rails at the rate of 6,000 to 8,000 tons per year. They have only recently started and are not yet in full operation. Their capacity is 15,000 to 20,000 tons per year. Their steel is of Lake Superior iron and is of excellent quality. The Freedom Iron and Steel Works at Lewistown, Pa., are producing rails for the Pennsylvania and other roads at the rate of some 8,000 tons per year. Their annual capacity is 10,000 to 12,000 tons. Their steel is pronounced by the Pennsylvania Railroad Company, after rigid tests, equal to the foreign. The Cambria Iron Company have a Bessemer steel works nearly completed at Johnstown, Pa. Its capacity will be 20,000 tons. The above statements are authoritative and clearly indicate that we shall be able, by next year, to produce annually at least 80,000 tons of good, American-made, steel rails, a fact full of promise for the future of American railways. It may also be stated here that the proprietors of one of the largest iron rail-making establishments in Pennsylvania, after struggling vainly for four years against the rising steel-rail tide, are now negotiating for the services of able and experienced German engineers and metal-workers, with a view to immediately establishing steel works, at which they confidently expect, within a year, to produce steel rails equal to the best for $75 a ton, which is less than the present price of good iron rails! The report quoted above states that some 7,000 tons of domestic steel rails have already been laid, and it is certainly safe to assume that 5,000 tons will be laid this season, making a total in round numbers of at least 12,000 tons (120 miles) of American steel rails in use in the United States at the end of 1869.

The great advantage of steel rails lies in their homogeneity. An iron rail, or a steel-headed rail, is made of a pile of bars heated and welded together, but a solid steel rail is rolled from a single ingot, and consequently is subject to wear only, whereas the others are exposed to "wear and tear," and the "tear," as any one must know who has ever noticed the battered, laminated, and disintegrated condition of iron rails, on a much used track, is a most serious consideration. So great is this advantage that a single steel rail has been known to outwear no less than 23 iron rails placed successively in the same track, and it is perfectly safe to say that any good solid steel rail will outlast a dozen rails of iron. The argument that steel rails are worthless when once worn out never had much force, and is now entirely upset by the discovery of the Martin process, by which old steel can be reworked with perfect ease. And the grand objection that steel is brittle, and, therefore, steel rails must break, is now fully overthrown by actual experience. Of course steel rails may be made so brittle as to be worthless, and it is well ascertained that punching holes in them has a most injurious effect; but this process is now discontinued, and it is certain that rails rolled from good Bessemer steel and drilled, instead of punched, are not only far more durable, but are at least as tough as the best iron rails.

Steel and Steel-Headed Rails.—The following is Mr. Abram S. Hewitt's circular to railway managers, containing the conclusions arrived at during his late investigations in Europe on this subject:

Having made a visit to Europe during the past summer, with Mr. John Fritz, Manager of the Bethlehem Iron Works, at Bethlehem, Penn., for the purpose, mainly, of acquiring information in regard to the use of steel for rails, I do not think that I can render a more acceptable service to the railroad interests of the United States than by making a brief statement of the conclusions at which we arrived.

First.—It appears to be certain that on all roads doing a large business, and especially where heavy engines are run at a high speed, steel must be substituted for iron, on the wearing surface of the track. The steel may be either puddled, or made by the Siemens-Martin, Bessemer, or crucible process; but, whatever kind of steel may be employed, care must be taken that the steel be of good quality, and adapted to the purpose. This demands skill in the manufacture, and care in the inspection. Unless this skill is used, and care exercised, there will soon be the same complaint in regard to the quality of steel as has existed in regard to the quality of iron.

Second.—For roads having a small traffic, iron rails are, as yet, more economical, provided light engines and moderate speed are employed. If proper care is used in the manufacture and inspection, and a price paid sufficient to cover the cost of good materials and workmanship, there is no more difficulty now than there was in former years in procuring iron rails of good quality. The real cause of the inferiority of modern rails appears to be due solely to the unwillingness of railroad managers to pay a price adequate to meet the actual cost of good iron and skillful work.

Third.—The question as to whether all steel rails, or iron rails with steel heads, should be used, is mainly one of first cost. There have been slight objections to steel-topped rails, when cast steel is used for the head arising out of the liability of the steel to separate from the iron, but this objection is now removed both in Europe and in this country, by the experience which has been gained at Dowlais in Wales, and at Trenton in New Jersey; and it is safe to affirm that steel and iron can be certainly united so as not to separate in the weld. The experience with the Booth rail on the New York Central Railroad also goes to show that it is not necessary to weld the steel and the iron at all, leaving it merely a question of prime cost as to whether the heads shall be welded or not. As to all steel rails, whether made from Bessemer, Martin-Siemens, or crucible steel, the only objection appears to be in their liability to break in very cold weather; but the percentage of such accidents is very small—and all things considered, it is difficult to decide whether this objection is of more weight than the possibility of a separation of the steel from the iron in the steel-topped rails.

On the whole, we came to the conclusion that we would take either the *all-steel* or the *steel-topped* rails properly made, giving the preference to the one which could be supplied at the lowest price per ton. In other words, we believe that the question of first cost should alone decide whether to use steel-topped rails or rails made entirely from steel, provided the quality of the materials used and the workmanship is equally good in both cases. The Siemens-Martin process has solved the only difficulty which existed in regard to steel rails when worn out, by working them over as the raw material for new rails. This process is now in operation at most of the leading works in Europe, and can be seen at work at Trenton, N. J., producing steel which welds perfectly to iron, and therefore admirably adapted for steel tops.

The Manufacture of Steel. — The Paris "Presse" says:—"An experiment of a most interesting character, and having the highest interest for the iron industry, has taken place at the Marquise Stock Works, in presence of two eminent persons of the Ecole Centrale. The object of this experiment was to make steel by one operation, a problem which has engaged all metallurgists, and if solved, would cause an industrial revolution. M. Aristide Berard, an engineer whose name is familiar to all who have occupied themselves with this question, proposed to change second class metal in course of refining into steel of at least ordinary quality, by means of a process alternately oxidizing and reductive. His efforts have been crowned with success. The product obtained by his process, in presence of two competent judges, proved to be steel of good quality, suitable for all purpose, and made with the facility necessary to its application to practical industry. The operation was effected in a reverbatory furnace, lasted about an hour and a half, and was accomplished with as much facility as puddling. In this process, instead of acting on 480 pounds of metal to obtain iron of number one quality, from 6,600 to 11,000 pounds of metal is made by only one operation into steel ingots ready for the workshop, and with an unexpected economy. We will be much deceived if this invention has not in it the germ of a complete revolution in metallurgy."

The Siemens Furnace.—In a paper before the Iron and Steel Institute, Mr. Josiah T. Smith, of the Barrow works, after noticing in detail the application and effect of the gases, added that for many months each producer at Barrow had volatilized 3 tons of coal per 24 hours, and that the greatest economy effected was when the consumption had not exceeded 50 cwt. Estimating the weight of one cubic foot of gas at the ordinary temperature of thin air to be .075 lbs., the volume of carbonic oxide, hydrocarbon and hydrogen, from one ton of coal would be about 53,000 ft., and the volume of nitrogen about 122,000 ft., or making together a total of 175,943 ft. The consumption of coal in the producers at Barrow being 500 tons per week, it gave an amount of gas passing through the tubes at the rate of 6½ ft. per second, of 87,000,000 cubic feet; or through the various furnaces adding the quantity of air there admitted of 6,600 tons. The saving of fuel by this process at Barrow was, over a period of two years, no less than 44 per cent ; but the actual money saving, by the use of a particular kind of coal, had been more than one-half. The yield of the gas furnaces, taken over the same period, showed a saving of 31 per cent as compared with the work at the firing furnaces, and the amount of repairs was just two-thirds of the old cost. In these three particulars was undoubtedly to be found the chief economy; but the adoption of the system enabled them to preserve greater cleanliness and order in their works, and an entire absence of smoke met a difficulty which, in the neighborhood of large towns, was every year becoming a greater grievance. There was, he admitted, a slightly increased outlay on the plant; but taking into consideration the increased capabilities as to quantity, it would be found to represent the difference in cost between the two systems.

Ironmaking in the Cleveland District.—For economizing the use of coke in the blast-furnaces their height has been increased from time to time, from 45 ft. to 95 ft. and upwards. Several of the original 45-ft. furnaces are still standing in the neighborhood of Middlesborough, but disused. It has been found at the five furnaces of Messrs. Bolckow and Vaughan that the furnaces of 95 ft. high and 16 ft. bosh are a little more economical as to the use of coke than the other three furnaces of the same height; two of them are 23 ft. and the other 22 ft. in the bosh; the capacity of the latter is about 20,000 cubic ft., and of the former about 10,000 ft. The production of pig-iron will not be in the same ratio, but is greatly augmented in the larger capacity. Another question of economy is the heat of the blast. It appears that with the blast heated to 1300° in high furnaces, 22 cwts. of coke are required in reducing 1 ton of pig-iron. and 1 cwt. of coke is saved for every 100° increase of blast, from 650° to 1150° and upwards. As the blast is heated invariably with the waste gases of the blast-furnace, this saving represents a direct economy in fuel. The blast-furnaces in the Cleveland district are closed at the top with bells, with the exception of the furnaces at Grosmont, the gases from which are withdrawn by means of chimney draught. At the furnaces of Messrs. Bolckow and Vaughan calcining kilns, 45 ft. high, 21 ft. in diameter, are erected of 18 in. fire-bricks, covered with ½-in. plates. The yield of iron from raw ore is about 30 per cent. One ton of coal will calcine about 40 tons of ironstone in these kilns; the calcined stone is let out from the bottom of the kilns direct into barrows. The coke is deposited in hoppers, and is let out at the bottom into barrows by sluices, and afterwards raised to the top of the furnaces. The mode of raising materials from the ground to the top of the furnaces in most cases is by water-balance, the supply water being pumped into a tank by a steam engine. Two works have hydraulic hoisting apparatus, some by pneumatic pressure, and others by direct steam power.—*Mining Journal.*

Krupp's Bessemer Rails.—The manufacture of Bessemer steel rails is now very extensively carried out in the works of Herr Krupp, at Essen. There are four converters used only for rail making. The steel ingots obtained are cylindrical, one ft. six in. diameter, and five ft. high. These ingots are hammered under a steam hammer of eight tons, and reduced to an octagonal section twelve in. wide. They are then rolled through a rolling mill worked by a 100-horse power horizontal and direct-acting engine. This engine, which is not condensing, runs at 50 revolutions per minute, and has a fly-wheel 46 ft. diameter, weighing 60 tons. The ingot is thus converted into a rectangular bar 5¾ in. thick and 7⅝ in. wide; this bar is divided into six or eight pieces, under a steam hammer of four tons. Each of these pieces is used for making rails; they are rolled through a steam rolling mill worked by a 500-horse power steam engine to the speed of sixty revolutions per minute. This system of manufacture enables us to get rid of the globules which have been ere now the most grievous defect of the steel rails, and which are more easily expelled from a large ingot than a small one.—*The Engineer.*

Wrought-Iron Chimney.—A new wrought-iron chimney has been recently erected at the Creusot Ironworks. It is 197 ft. high and 6 ft. 7 in. diameter. At the bottom the diameter is increased to 10 ft. by a curved base, which is fastened by vertical bolts to masonry work. The thickness of the sheet-iron is 3-32 in. at the top, and 7-16 in. at the bottom. There is an inside iron ladder. The weight of this chimney is 40 tons; it has been riveted horizontally, and lifted afterwards with a crane. Another one, 275 ft. high, will be soon erected, but by a different system; it will be riveted vertically, with an inside scaffolding. These chimneys are built for an extension of the Creusot Works, especially intended for steel making. There will be eight Bessemer converters, where the cast-iron will be run direct from the blast-furnace; there will be also many Martin's furnaces, and an extensive workshop for melting steel in crucibles, where it will be possible to melt together 50 tons of steel.

Accident at a Bessemer Works.—A serious accident has occurred at the Atlas works, belonging to Messrs. John Brown & Co. (Limited) at Sheffield. Six men were engaged in casting an immense ingot, when the vessel, which contained about seven tons of molten metal, was overturned, in consequence of the chain which balances it giving way. The whole of the red-hot steel was cast upon the floor. Three workmen were very severely burned. The metal spread all over the floor of the workshop, which is situated in the Bessemer department of the manufactory, and several other workmen, who were some distance from the moulding apparatus, had very narrow escapes.

Production of Rails in France.—A table which has been prepared in illustration of the production of rails in France during the last ten years presents the annexed results: 1859, 101,426 tons; 1860, 121,438 tons; 1861, 164,371 tons; 1862, 216,175 tons; 1863, 226,948 tons; 1864, 215,983 tons; 1865, 184,131 tons; 1866, 159,061 tons; 1867, 154,351 tons; and 1868, 202,204 tons. The average price per ton in 1859, was £10 2s. per ton, while, in 1868, it had fallen to £7 2s. per ton.

British Blast-Furnaces.—The number of furnaces in blast, in 1868, was 560; and the make of pig iron in Great Britain amounted to 4,970,206 tons, an increase of 209, 183 tons over 1867. In England the make was 2,970,905 tons, an increase of 159,959 tons; in Wales and Monmouthshire, 931,-301 tons, an increase of 12,221 tons; in Scotland, 1,068,000 tons, an increase of 37,000 tons.

Magnetization of Iron and Steel.—At a recent meeting of the Academy of Sciences, at Vienna, Herr A. Waltenhofen read a paper on the limits of the magnetization of steel and iron. As a general result he finds the potential temporary magnetization of iron to be about five times greater than that of the best steel.

Catasaqua Manufacturing Co.'s Iron.—Tests at the Scott foundry, Reading, give specimens of three brands of this iron—66,000 lbs., 68,400 lbs. and 74,600 lbs. tensile strength, respectively.

Steel Boilers.—Messrs. D. Adamson & Co. are now making steel boiler shell rings in one plate, measuring 27 ft. in length, and weighing upwards of 16 cwt. each.

ORDNANCE AND NAVAL NOTES.

The "Inconstant."—This fine frigate, of 4,060 tons measurement, 1,000-h.p. (nominal), carrying as her armament ten 12 ton 9 in. and six $6\frac{1}{2}$ ton 7in. muzzle-loading rifled guns, mounted on iron carriages and slides—the pioneer of the new type of unarmored iron-built war frigates introduced into the English navy by the present Chief Constructor —has been put through her official speed trial at her load draught of water over the measured mile in Stokes Bay, near Portsmouth, and by the exceptionally high rate of speed she attained more than confirmed the strongly favorable opinions of her powers created by her previous performance on her preliminary trials, and also exceeded the estimate of her speed given in officially to the Admiralty by her designer. The speed trials of the Inconstant are without doubt the most important by far of all that have yet been made over the measured mile in this country. She is a war frigate designed for special services, requiring exceptional speed under steam, and in all respects intended for competition with the flying unarmored war frigates lately added to the American Navy, and whose powers for offense and flight under steam have been so highly eulogized in the official documents reporting upon their trials and handed in by the officers conducting them to the secretary of the United States Navy. In the American official documents the Wampanoag was said to have steamed at the rate of 16.7 knots per hour for 37 consecutive hours, in a strong beam sea and wind, over a given distance along the coast line. This was stated in the reports to have been done by the Wampanoag, at her proper seagoing trim, and with all weights on board; but now this is flatly contradicted on this side the Atlantic, and the Wampanoag is asserted to have attained her extraordinary rate of speed under conditions different from those given in the official reports. It would be of some value to us to learn the exact truth relating to the trials of the American unarmored frigate, in order that we might obtain some reliable standard by which we could measure the value of our own frigates of a similar character. Sixteen and three-quarter knots per hour continued for 37 hours by the Wampanoag is, on the face of the assertion, an almost incredible performance for any ship carrying 15 in. guns and exceptionally heavy weights in engines and boilers, unless she was greatly assisted by her sails, and until some precise information be given as to how the distance run in the 37 hours was arrived at, the Wampanoag will be only considered really to be what she is asserted to be in this country—a 14 knot ship; and in that case the Inconstant is the faster ship of the two by $2\frac{1}{4}$ knots per hour.

On weighing her anchor from Spithead for her trial the Inconstant drew 20 ft. 8 in. of water forward and 24 ft. 7 in. at the stern. She did not carry her crew, powder and shell, and a quantity of stores, but the weight of all these matters was placed on board for trial in the shape of iron ballast, and, in addition, she carried about 40 tons extra weight in coals, &c., so that her trials were made at a draught of water an inch or so in excess of what it will be when the ship actually proceeds to sea.

Subjoined are the results of the trial. Full boiler power, measured mile runs:

No. 1.—Speed of ship, 16.901 knots; revolutions of engines—per mile 259, per min. 73.5; steam, 30 lbs.; vacuum—forward 25.5, aft 25.5.

No. 2.—Speed of ship, 15.385 knots; revolutions of engines—per mile 287, per min. 74; steam, 30 lbs.; vacuum—forward 25.5, aft 25.5.

No. 3.—Speed of ship, 17.822 knots; revolutions of engines—per mile 252, per min. 75; steam, 30 lbs.; vacuum—forward 25.5, aft 25.5.

No. 4.—Speed of ship, 15 knots; revolutions of engines—per mile 298, per min. 75; steam, 31 lbs.; vacuum—forward 25.5, aft 25.5.

No. 5.—Speed of ship, 18.367 knots; revolutions of engines—per mile 269, per min. 75.5; steam, 30 lbs.; vacuum—forward 25.5, aft 25.5.

No. 6.—Speed of ship, 14.754 knots; revolutions of engines—per mile 304, per min. 75.5; vacuum—forward 25.5, aft 25.5.

Mean speed of the ship under full boiler power, 16.512 knots per hour! Mean revolutions of the engines during the six runs, 74.48 per minute; mean steam pressure, 28.825 lbs.; indicated power by the engines, 7,343 horse.

Full boiler power circles, 12 men at the wheel:

To Port.—Half circle made in 3 min. 25 sec.; full circle made in 6 min. 48 sec.

To Starboard.—Half circle made in 3 min. 11 sec.; full circle made in 6 min. 10 sec.

Half boiler power, measured mile runs:

No. 1.—Speed of ship, 15.789 knots; No. 2.—Speed of ship, 11.613 knots. Mean speed of the ship under half boiler power, 13.701 knots per hour; mean revolutions of the engines, 59.95 per minute. Mean steam pressure, 14.227 lbs.; indicated power by the engines, 3,532.29 horse.

Half boiler power circles, 14 men at the wheel:

To Port.—Half circle, 3 min. 56 sec.; full ditto, 7 min. 50 sec.

To Starboard.—Half circle, 3 min. 42 sec.; full ditto, 7 min. 6 sec.

The Inconstant has a balanced rudder like the Bellerophon. Hercules and Captain, but in her case the fore part of the rudder was reduced in area very considerably the last time she was in dock, and perfect command is now kept over the ship by the men at the wheel, however far the helm may be put over. On her light draught trial the vibration on board was found to be very great, but since the ship has been brought down deeper in the water this has been materially lessened and when the engines were being driven at their highest speed, the vibration exhibited by the hull of the ship was nothing at all extraordinary or beyond what is usually felt under such circumstances. The engines, which were in charge of Messrs. Anderson and Knight, as the representatives of the manufacturers Messrs. John Penn & Son, gave satisfaction in every respect to the Government officials on board.—*Artizan.*

War Expenditure.—The annexed table is extracted from a paper on war taxation, by Mr. William Stokes, which was recently read before the National Reform Union, at Manchester. Mr. Stokes' object was to set forth the permanent consequences of what he terms profligate war expenditure and periodical invasion panics. The conclusion he draws from the figures is that the industry, trade and manufactures of Great Britain are more shackled and burdened by needless taxation than those of any other nation :

	National debt. £	Amount per head. £	s.	d.
1. Ducal Hesse	228,916	0	5	4
2. Sweden	4,114,880	1	0	0

The North German Fleet.—The Imperial Navy of North Germany dates its origin from the year 1848, when the Danish war demonstrated to Prussia the necessity of establishing a fighting fleet and showed the position of a nation lacking this branch of military power. Denmark, a country insignificant in comparison with the German Principalities, was enabled to inflict vital injuries which they were powerless to prevent or to resent. At first the want of union among the German States made itself very strongly felt during the establishment of the fleet, and instead of a combination of all the resources at command they were wasted to create two navies—one in the North Sea, and a Prussian fleet in the Baltic. And all the money which could be gathered for the purpose was absorbed without a German fleet being created. In despite, however, of all these unfavorable circumstances the Prussian navy has so far increased, during the last twenty years, that it has developed from an insignificant fleet of gunboats to a marine, comprising thirty steam and six sailing ships, besides gunboats and vessels for harbor defenses. The navy comprises the fighting and training ships, transports, coast-guard vessels, and those for the defences of ports and harbors. Of the first named, five are armor-clad—the rest of wood, which are still considered capable of good service; the training ships being for the most part disrated sailing vessels, in which officers and seamen receive their professional training.

The following table shows the actual strength of the effective navy of North Germany :

Name of Ship.	No. of guns.	Horse power.	Tonnage.

Besides these there are five vessels for harbor service, thirty-two yawls armed with two guns, and four with one gun each.

Two corvettes are in course of construction—the Hansa, with an armor-plated battery of eight guns, and of 450 horse power; and the Ariadne, a wooden ship, with a battery of six guns and with 360 horse power. Altogether the Prussian navy possesses 90 armed vessels of all denominations, mounting, collectively, 1,549 guns; but few of these, however, were built at any of the Imperial dockyards.—*Engineering.*

Shoeburyness Experiments on Shells and Fuses.—A series of experiments were recently conducted at Shoeburyness, with the object of ascertaining the relative efficiency of the Palliser shells, having their heads chilled and bodies cast in sand, the merits of shells made of Firth's steel, and containing large bursting charges, and to determine the reliability of a new form of fuse designed by Lieutenant E. Boxter, R. N. All the rounds were fired from the 9 in. Woolwich rifled gun, with full battering charges of 43 lbs., at a range of 200 yards, against an 8 in. plated target, with 18 in. teak backing and $\frac{3}{4}$ in. skin. Five rounds were fired with the compound Palliser projectile (having the chilled head and soft iron body), and two rounds with shells of Firth's steel, the first, third, fifth, sixth and seventh rounds being with the former, and the second and fourth with the latter class of projectiles.

In the first round the Palliser shell effected a penetration of 22 in. from the back of the head, which remained in the hole, the body being blown out in front of the target.

In the second round with a hardened Firth steel shell, penetrated to a depth of 26 in., the shell bursting in the backing, and the body being blown out of the shield.

The third round with a Palliser shell, penetrated to a depth of $25\frac{1}{2}$ in., tearing away the backing, and tearing some of the backing girders.

The fourth round, a Firth's steel shell, penetrated to $8\frac{1}{4}$ in., making a hole 10 in. by 11 in. The effect of this round manifested itself in stripping off flakes of the plates in the vicinity of the point of impact.

The Boxer fuse, which has been adapted to the Palliser shell, is intended to be used in those projectiles which are fired against wooden or thinly-plated ships, which are now penetrated by shell with the same effect as by solid shot. The fuses are made of gun-metal, and are screwed into the rear of the shell through a gun-metal bushing. In the front of the fuse plug, in a cylindrical recess, is placed a small cylinder of lead behind a gun-metal hammer, which is suspended by a wire. In front is placed the fulminate upon a disc in contact with a pellet of compressed powder. When the gun is discharged the leaden cylinder is compressed, and the hammer is liberated by the shearing of the wire which suspended it, and so soon as the shock of impact occurs, the hammer springs forward, and, striking the fulminate, explodes the shell by means of the powder pellet. The act of explosion, however, occupies a space of time sufficient to allow of the passage of the projectile through the wooden sides or the thinly armored walls of a ship.

Three experimental rounds were fired with shells provided with these fuses with the object of ascertaining whether the efficiency of the Palliser projectile would be impaired when fired against thick plates. In all these rounds a complete peuetration was effected, as well as a marked superiority in the amount of damage.

The experiments of the day were completed with some rounds fired from a 9-pounder Indian brass field gun, to ascertain the value of a new fuse, being a combination of the service Boxer wood time fuse and a modification of Captain Freeburn's concussion fuse, adapted for light field pieces as well as for heavy guns—*Engineering.*

Pontoons for Transport Ships.—About two years since Admiral Mends proposed the construction of pontoons for the service of the new very large transport ships Serapis, Euphrates and Crocodile. The first pontoons which were constructed for the Serapis were of cylindrical form, and were built of steel by Maudslay. Four were made to constitute the raft, the weight of each being about $2\frac{1}{4}$ tons. On the trial of them before the naval and military authorities at Woolwich, it was suggested that pontoons constructed of Mr. Clarkson's cork material would possess qualities of lightness, strength, and buoyancy peculiarly suitable for the operations such pontoons would be called upon to perform, and that they would also be more easily repairable if damaged by musketry fire. Four pontoons of the following dimensions were ordered for experimental trial, and these were launched into the Thames on Monday last. Their dimensions are: Length, 36 ft.; diameter, 4 ft. 6 in. A light framework is made of wood as the skeleton of the structure. The form is then completed by planking of $\frac{1}{4}$ in. thick pine wood, both sides of which are covered by stout canvass adhering to the surfaces by a waterproof solution. Over this sheet cork is applied by the same adhesive substance; the whole pontoon is coated with the solution, and a strong jacket of canvass is superadded as the external covering. The advantage of this material is that it possesses elasticity and such capacity of cushioning blows that the vessel receives no injury from such concussions as would be liable to fracture or indent metal structures; and with the passage of shot there is an absence of splinters, and a natural tendency on the part of the cork material to close up the orifice made by the missile. The four pontoons were manufactured in London, and floated down the river to the factory of Messrs. Maudslay, Sons and Field, where they were fitted together by spars and lashings, and a stage or platform for landing or embarking guns, troops, horses, &c., erected upon them. The pontoon was then towed down by the Bustler, Admiralty steam tug, to Woolwich dockyard.

THE TURRET SHIP MONARCH.—The following notes of the dimensions and performance of the two-turret armored ship Monarch will be found of interest:

Length between perpendiculars...	330 ft.
Extreme breadth................	57 ft. 6 in.
Depth of hold..................	18 ft. 8 in.
Tonnage........................	5,102 tons.
Draught load on trial—forward...	21 ft. 10 in.
" " —aft.......	25 ft. 8 in.
Displacement "	8,070 tons.
Engines, nominal HP...........	1,100.
Cylinders, diameter.............	120 in.
" stroke............ ..	4 ft. 6 in.
Indicated on measured mile......	7,842 HP.
Revolutions, mean "	63.61 "
Indicated on six hours' trial......	7,470 "
Revolutions, mean, six hours' trial,	62.67 "
Steam in boiler, measured mile....	31.33 lbs.
" " six hours' trial....	30.58 "
Midship section.................	1,208 sq. ft.
Mean speed, measured mile......	14.937 knots.
$\frac{V^3 MS}{I H P}$ "	513.4
$\frac{V^3 D^{\frac{2}{3}}}{I H P}$ "	171
Mean speed, six hours' trial......	14.715 knots.
Co-efficients as above............	515.3 and 171.6.

The Monarch has nine boilers, containing forty furnaces, the area of grate being 770 sq. ft., while the total heating surface is 20,900 sq. ft. There are 3,600 sq. ft. of superheating surface, and the surface condensers present 16,500 sq. ft. of surface. The Griffiths' screw is 23 ft. 4 in. in diameter, and 26 ft. pitch. The armament of the Monarch consists of two 25-ton rifled guns in each turret, besides three smaller guns on deck. Each turret is 26 ft. 6 in. in external diameter, and 22 ft. inside, the solid rolled plates around the ports being 10 in. thick, while at other parts of the turrets the thickness is 8 in.—*Engineering.*

THE STEVENS BATTERY.—The celebrated "Stevens Battery" is still at the yard in Hoboken, where her keel was laid long ago. The ban of secrecy has not yet been removed from the work on the vessel, which, however, is still steadily progressing. Our reporter visited the yard yesterday, and was enabled to gain a few facts in regard to the construction of this modern marine monster. The vessel as she stands is 250 ft. in length, 30 ft. in breadth and draws 27 ft. of water. Her hull is composed of teak wood two feet in width, with a covering of four inches of iron, which is screwed on with copper bolts. Her decks are composed entirely of iron, and the battery which she is to carry, is to consist of four guns of enormous caliber, throwing a solid ball of 700 pound weight. She will have two screw propellers, and it will be impossible for her to turn within a space equal in length to that of the vessel. General McClellan is at present superintendent of the work, and he has 180 men employed. The ram is to be completed during the year 1871, when it will be presented to the State of New Jersey, as a protection to New York Harbor. Thus, says a New York Daily, very correctly, only the length of the vessel is 420 ft. instead of 250, and 45 ft. beam instead of 30; and she is built of iron instead of teak.—ED. V. N. M.

IMPROVEMENTS IN MUSKETS.—The equipment of a musketeer, as late as 1689, was very cumbrous. He was provided with a heavy wooden fork, which he had to stick into the ground with the prongs uppermost, to serve as a support for his matchlock, which he had to load with his powder-horn and measure, keeping the ball meanwhile between his lips. The wadding he had to get from his hat. Nevertheless, the wheel-lock, provided with pyrites instead of flint, had long been invented, but seems never to have come into general use in armies, except for cavalry pistols. The French lock which preceded the percussion system was invented as early as 1640, though it, of course, received successive improvements. But even before that time Gustavus Adolphus had introduced a great improvement in musketry, by reducing the weight of the piece to 10 lbs. instead of 15 lbs. This enabled the soldier to do away with the fork, and therefore increased the rapidity of the fire. The bullet weighed an ounce. Another improvement of his was the paper cartridge, which, however, at first only contained the powder, the bullets being kept in a bag.

PALLISER MORTAR.—A 13 in. sea service mortar of five tons weight has been ordered to be converted upon Major Palliser's plan into a 9 in. rifled mortar of about $6\frac{1}{4}$ tons weight, to fire the 9 in. service rifled shell, which contains a bursting charge of 18 lbs. of powder. The bore of the mortar will be elongated to about 4 ft. 6 in.; and a range of about 7,000 yards is expected to be obtained from a charge of 20 lbs. of powder. Some further experiments are being carried on with two 10 in. shell guns, which are being converted respectively into an 8 in. and a 7 in. rifled gun, in order to determine the most suitable caliber for the conversion of cast iron 10 in. shell guns. The whole of the 212 8-in. guns converted into 6.3 in. rifled guns by Sir Wm. Armstrong & Co. have been passed into the service, and 200 more are in course of conversion in the royal gun factories. It is probable that a considerable number of guns will be converted next year for land defenses, the whole of the above 437 guns being for the navy.

HARVEY'S SEA TORPEDOES.—A considerable number of these formidable machines have been supplied by the maker, Mr. William Nunn, of St. George street, London Docks, to the Russian Government.

Foreign 20-in. Gun.—Some interesting experiments have taken place at Perm with a new 20 in. gun, cast in the foundry of that town. The trials made with this gun, under the direction of Major General Prestitch, commandant of the Cronstadt artillery, are described in the officiale rports as having been very successful, and more satisfactory in their results than had been the case with American guns of the same caliber. The gun was fired 314 times; the projectile weighs 10 cwt., and the charge of powder required for each shot was 130 lbs. The weight of the gun is about 50 tons, the recoil 7 ft., the initial velocity of the projectile 1120 ft. per second, and the percussion force at a distance of 50 ft., about 10,000 tons. The official papers say this is ' the most powerful gun in Europe.

Explosive Compounds.—Mr. F. A. Abel, has communicated a long paper to the Erench Academy on the properties of explosive compounds, which contains the results of experiments with gun-cotton, gun-powder, nitro-glycerine, &c. He accounts for the difference remarked in the nature of the explosion produced by various substances when they act upon matter of a different kind by supposing that the explosion produces a certain kind of vibration that may or may not be synchronic with that produced in the body operated upon by the explosion.

Armstrongs for Greece.—The screw steamer Hotspur has lately sailed from Lynn for the Tyne, and taken on board a cargo of Armstrong guns. These Armstrongs are intended for the Greek government.

RAILWAY NOTES.

Great Western New Narrow Gauge Engines.—The following are the principal dimensions of the new locomotive engines of the Great Western Company. The boiler is 10 ft. 6 in. in length, and 4 ft. diameter inside. It is of 7-16 in. plates, the tube plates are $\frac{5}{8}$ in., the angle irons $3\frac{1}{2}$ in., the rivets $\frac{3}{4}$ in. diameter, are $2\frac{1}{8}$ in. between centers; there are six stays of an inch diameter, and two gusset stays. The outside fire-box is 5 ft. 1 in. long, by 4 ft. $1\frac{1}{4}$ in. broad, and as regards height is flush with the barrel; it is 2 ft. 8 in. below the boiler, and is of 7-16 in. plates, bound by $\frac{3}{4}$ in. rivets at $1\frac{7}{8}$ in. centers; it has 540 stays $\frac{7}{8}$ in. diameter; the distance of the copper stays apart average 4 in. The inside fire-box is of copper, and is 4 ft. 6 in. long by 3 ft. 6 in. wide, and is 5 ft. 6 in. from the bottom to the top of the box; it has nineteen fire-bars 1 in. distance apart; the area of the fire-grate is 15.75 ft. The superficial area of the box is 87 ft.; the steam-pipe is 5 in. diameter. The tubes, iron, are 10 ft. $9\frac{3}{4}$ in. long; in outside diameter 2 in. and $1\frac{5}{8}$ in.; they are $2\frac{5}{8}$ in. between centers, and in number are 161 of 2 in. and fourteen of $1\frac{5}{8}$ in., or 175 in all, giving a superficial area of 999 square feet, and a total heating surface of 1,086 square feet. The smoke box is 2 ft. $5\frac{3}{4}$ in. in length, by 4 ft. $8\frac{1}{2}$ in. broad, and of $\frac{1}{4}$ in. plate. The chimney is 1 ft. 4 in. diameter, of $\frac{1}{8}$ in. plate, and has an extreme height of 14 ft. 6 in. above the rail. The blast pipe, of cast iron, is $4\frac{3}{4}$ in. diameter at the top, and is 3 ft. 6 in. high. The pumps, brass have a 2 ft. stroke with a plunger $1\frac{3}{4}$ in. diameter. The diameter of the waterway is $2\frac{1}{4}$ in.; distance of centers, 3 ft. 7 in.; rise and fall of pump clack seat 3-16 in. The safety valves, brass conical, are 4 in. diameter, with 3 ft. centers of levers. The cylinder is 16 in. diameter; stroke, 2 ft.; distance of centers, 2 ft. 3 in.; distance below boiler, 1 ft. $5\frac{1}{2}$ in.; distance of centers of valve spindles, $4\frac{1}{2}$ in. The back and front flanges have ten bolts, $\frac{7}{8}$ in. diameter, in each. The cylinder is $\frac{7}{8}$ in. thick; the piston rod $2\frac{1}{2}$ in. diameter. The distance between inside of ports is 2 ft. $1\frac{1}{2}$ in. The ports are 1 ft. 2 in. in breadth; length of steam, $1\frac{3}{8}$ in.; length of exhaust, $3\frac{1}{2}$ in.; thickness of bridge, $\frac{3}{4}$ in. The slide valves travel 4 in.; the lead is 3-16 in. to 5-16 in.; lap on steam side, 1 1-16 in.; and the eduction overlap, $\frac{1}{8}$ in. The four eccentrics of cast iron, with patent white metal rings, have 3 1-16 in. throw; diameter, 1 ft. $2\frac{7}{8}$ in.; breadth, $3\frac{1}{4}$ in. The regulator, cast iron, with brass slide, has two steamways, $6\frac{1}{2}$ in. by 1 in. The motion bars are 4 ft. $2\frac{3}{4}$ in. long, 3 in. broad, and $2\frac{7}{8}$ in. apart. The driving-wheels are 5 ft. diameter; the outside tire is $5\frac{5}{8}$ in. broad by $2\frac{5}{8}$ in. thick; the wheels are 4 ft. $5\frac{1}{2}$ in. apart; and the cone of the wheel is 1 in 15. The leading wheels are 3 ft. 6 in. in diameter; distance of wheels same as the driving-wheels; cone of wheel, 1 in 10. The trailing wheels are 5 ft. diameter, same distance apart; cone 1 in 10. The distances of the centers of the wheels are—driving-wheels from leading wheels, 7 ft. 3 in.; driving-wheels from trailing wheels, 8 ft. The laminated steel springs for the driving axle are 3 ft. $5\frac{1}{2}$ in. long by 4 in. broad, and consist of fifteen plates, giving a depth of $5\frac{3}{4}$ in. at the center. The springs for the front axle have seventeen plates, and are $6\frac{1}{2}$ in. thick in the center. The extreme length of the frame is 25 ft. 2 in., and the breadth 4 ft. $4\frac{3}{8}$ in. The buffers are 3 ft. 3 in. in height from the rail, and 5 ft. 10 in. between centers. The suction pipes, of copper, are in height 1 ft. 3 in. from the rail; distance of centers 3 ft. 9 in.; diameter of waterway, $1\frac{3}{4}$ in. A tender to these engines needs no description, seeing that they have none. They (the engines) are supplied each with two tanks fixed on platforms over the frames; the capacity of the tanks is 395 gallons each. Coal is carried in a bunk at the back of the foot plate. The tank capacity of an engine, it will be seen, is 790 gallons, but in practice they are never charged with this quantity. The tanks are usually filled to a height of about 13 in. from the top, this restricted height being found necessary for the efficient working of the condensing apparatus. With water to this level, and with coke and sand-boxes full, ready for a trip, the loaded engine is 33 tons 4 cwt. in weight, borne thus:—Leading wheels, 9 tons; driving wheels, 12 tons 2 cwt., and trailing wheels, 12 tons 2 cwt. The weight is reduced to about $31\frac{1}{2}$ tons at the end of a moderate journey. These engines, it may be repeated, have more than fulfilled all the expectations that were entertained concerning them when they were designed and constructed. We have already had occasion to speak favorable of them in our impression for May the 14th. The weight of the various engines now working the Metropolitan Railway, is about as follows:—Metropolitan Company's engines, 42 tons nominal; Midland engines, 45 tons nominal; Great Northern engines, 33 tons nominal; Great Western narrow gauge, 33 tons 4 cwt. actual.—*The Engineer.*

UNDERGROUND RAILWAY LOCOMOTIVES. — Mr. Buckhout, in his report on the New York City Central Underground Railway, describes a general design, and comments as follows:—Gauge, 4 ft. $8\frac{1}{2}$ in. Fuel, anthracite coal or coke. Cylinder, 14 by 22 in., four 56-in. driving wheels, steel tyres, all flanged. Two single axle radiating trucks, one at each end, wheels 30 in. in diameter. Furnace of steel; 126 two-in. flues, 10 ft. 5 in. long. Tank on each side of engine to contain 1,500 gallons. The engine also to be supplied with a blower or steam jet. The engine to be so arranged as to throw the exhaust steam into the tanks so as to condense it, or throw it up the chimney for the purpose of blast for raising steam, and so that the engineer can make the change instantly as required. This engine will take 80 tons in addition to its own weight (68,000 lbs. in running order), with 1,500 gallons of water in the tank, and 600 lbs. of coal, up grades of 1 in 39, or 38 ft. per mile, with a pressure as low as 80 lbs. per in. (if the steam should get so low), cutting off at 60 per cent admission, it being intended to carry a maximum of 130 lbs. per inch. About 1,400 gallons of water will be required for the condensation of the steam for the distance of two miles. consequently it would require changing every four miles, if the steam were condensed for half that distance. The tanks to have a discharge valve by which the water can be let out quickly, when it requires changing. The fixed wheel base to be 6 ft 9 in., and the whole base, including the radiating trucks at each end, to be about 21 ft. 9 in. With this arrangement the truck wheels will not require to radiate over $3\frac{1}{4}$ in. from a straight line, on curves of 200 ft. radius, which is much within the limits of its capability. With equalizing levers, as applied to this description of engine by Mr. Hudson, two-thirds or more of the weight can be carried on the drivers, and the arrangement is such as to accommodate itself to all the vertical and lateral undulations of the track, without varying the distribution of the weight on the wheels; it is also arranged so as to be equivalent in action to a four wheel center bearing truck at one end, and to a four wheel side bearing truck at the other end. In addition to these properties the engine can be run either end foremost with *great facility and equal safety*: a feature not embraced in any four driving wheel single truck engine. It has therefore special advantages in saving the time usually occupied in turning an engine around so as to run truck foremost. It has another advantage. The trucks do not deviate from the center line of engine nearly as much as a faur driving and four wheel swing truck engine does on the same curve, being some 50 per cent in favor of the double truck.

COAL AND SMOKE CONSUMPTION, ON THE PENNSYLVANIA RAILWAY.—In 1859, arrangements were made for a thorough and favorable trial of the Gill patent for smoke and gas consumption, and in the Report for that year (13th A. R.) the Master Mechanic expressed himself as satisfied that "the true secret of consuming smoke has been discovered and rendered practicable." This plan included a "combustion chamber," which it was hoped could be dispensed with—a fire-brick deflector being introduced, involving the same principle. Supt. Scott was also sanguine that a saving of 50 per cent in the cost of fuel could be effected. Although the results are favorably spoken of in the late Report (14th A. R.) it does not appear that the end was attained, although the deflector which was largely introduced (costing $50.00) was regarded as economical, on account of enabling the Company to go back to the plain fire-box which, aside from possessing conditions favorable to combustion, was accessible for inspection and repairs. In the same year (1863), experiments were made with anthracite, an engine being built expressly therefor, with the latest improvements, but it was found that this fuel would not make steam freely enough on long, fast runs with heavy trains. Experiments are now making with an apparatus for bituminous coal, invented by J. T. Rich, of Philadelphia, who puts into the fire box a "dead plate," extending from side to side, sloping from a short distance beneath the door, and then turning down perpendicularly to the great-bars. Above is a fire-brick arch extending from the back well forward, around which the ascending flame must pass toward the front. Outside the door is a hopper, constantly supplied with coal, which it passes in, as that already in the fire-box works down to the dead plate. A fire being started on the great cokes, the coal on the dead-plate; and the heat is utilized by passing around the arch and through the flues. As the coke thus made itself burns away—its heat and gases, without smoke, passing through the flues—new coal constantly works down and undergoes the same process. The experiments thus far show there is no doubt that the process will result in almost entire freedom from smoke; but the practical question whether steam can be made fast enough, is not yet decided. Experiments are also making with coke already prepared; and it is deemed certain, should Mr. Rich's device not succeed, that coke, which can be obtained at morderate cost will be successfully used.—*Chicago Railway Review.*

UNIFORMITY OF LOCOMOTIVES.—The "American Railway Times" makes the following statement which was doubtless intended to be severe:

"Two years ago the Pa. R. managers determined to reduce their rolling stock down to some such simple system as we have indicated; and they have succeeded in reducing the varieties of engines down to 40, in a total equipment of 456 engines. This may be called a *reductio ad absurdum.*

Truly to your genuine nothing-if-not-critical Boston art, "Seneca cannot be too heavy, nor Plautus too light." The "Times" borrowed, and isolated, an expression in the "Review's" article, and chose to interpret it without reference to the full accompanying explanations. The 456 locomotives on the road are all referable to these three classes:

1. *Standard Passengers,* having 17x24 in. cylinders, and $5\frac{1}{2}$ ft. drivers.

2. *Standard Freight,* 40-wheel, having 18x22 in. cylinders, and $4\frac{1}{2}$ ft. drivers; and,

3. *Standard Shifting,* 6-wheel, having 15x18 in. cylinders, and 44 in. drivers.

Of the first class, there are two modifications—the Mountain Helper, having 18x24 in. cylinder, 5 ft. drivers, and large boiler; and a local and fast freight engine differing only in the diameter of the driver, 5 ft.

Of class 2 there is but one modification—a Mountain engine having 4 ft. drivers, and larger boiler. These are the only *classes* recognized; and of all these, the important working parts (castings) are interchangeable—such as driving-boxes, eccentric stops, etc. Of *patterns* there are still well nigh as many as of manufactures; but these embrace only those which have been many years in use, and to have changed which to uniform standard or *pattern* would have necessitated their cutting-up long before this time of service had expired. The P. R. like most roads in the beginning, purchased engines of many different manufacturers; and as these wear out, their patterns disappear, so that within a few years there will be not only one invariable standard of construction, but of style.—*Cor. Chicago Railway Review.*

Improved Locomtive Alarm Bell.—There has been a recent trial on the Detroit and Milwaukie Railway, of an invention or device for ringing the locomotive bell continuously. The device consists of placing an ordinary bell, weighing about 100 lbs., on the front of the locomotive just over the cow-catcher. A rod attached to the eccentric shaft causes a clapper to strike the bell each turn of the driving-wheel. The bell is suspended loosely, and revolves from the force of the stroke it receives, so that all parts of its surface are equally exposed to wear.

The advantages of this arrangement are a continuous sound, slow or rapid in proportion to the speed of the engine, each revolution of the wheel producing a stroke of the bell. In case of accident the railway company can always prove that their bell was ringing according to law, that being the point most difficult to convince a jury, and the one which railways have the greatest difficulty in proving. Owing to the position in which this bell is placed—in front of the engine and about three feet from the ground—the sound can be distinctly heard about three miles in day time, and by night four miles or more, the ground and the continuous rail, both excellent conductors of sound, assisting in carrying the vibrations. The bell may also be rung, if necessary, by a cord from the foot board when the engine is at rest. Quite a number of these bells have been placed on the engines of the Detroit and Milwaukie Railway, and several other companies are giving them a trial. The inventor is Mr. Ben. Briscoe, the master mechanic of the Detroit and Milwaukie road, who has charge of the locomotive works of the company at Detroit, Michigan. He is one of the numerous graduates from the Baldwin Locomotive Works at Philadelphia.—*American Railway Times.*

Iron Cars.—The "Ironmonger" suggests the desirability of constructing trains wholly of iron. They might be so constructed of this material as certainly to offer greater power of resistance in case of collision, and this without materially augmenting their weight, whilst the danger from fire would be almost nil. With strong frames, properly braced, the sides might be covered with comparatively thin sheets of iron. Railway companies cannot certainly be expected, in view of the large intermediate outlay that would be involved in an entire change of rolling stock, to carry out at once the suggestion, but the transformation might be effected gradually, and all carriages hereafter constructed might be of iron. These iron cars would doubtless be more lasting, and, in the end, more economical. Our large iron manufacturers would do well to give this subject their attention.

The Shops of the Pacific Railway at Sacramento.—There are now 160 locomotives at the western end of the road—belonging to the Central Pacific Company—of which 29 can be accommodated at one time in the Sacramento round-house. Its front measures 611 ft.; its rear, 411 ft.; depth, 64 ft.; and height, 24 ft. Water for the engines is supplied from a side tower, called the oil-house, in the top of which is a tank containing 65,000 gallons of water, and below the same two stories for offices, and a cellar which holds seven great sheet-iron 1,000-gallon reservoir for oil, thus secured against fire.

The wood-working and car manufactory is another colossal building, 90x238 ft., of two colossal stories, with straining-beam truss roof, whereby the lower story is kept entirely free and unobstructed. There is also an L 45x90 ft. All the cars, including doors, windows, and upholstery, are made from California material, at a cost quite as low as that of the same articles imported. Numerous band-saws and other of the most complete modern wood-working machines may be seen at work.

The machine-shop is 100x205 ft., beautifully roofed, and filled with superb iron-working machinery adapted to railroad uses. This shop is intended to do all the iron-work of the road, but local repairing, for which shops have been built along the line—as at Rocklin, the "foot of the hill," where there is also a first-class granite round-house, and where two or three additional engines are in readiness to join the single one that does duty for fifty or sixty cars between Sacramento and that place. In the machine shop there are eleven pits, adapted for locomotive repairs, and a traveling bridge, by which locomotives can be picked up and lifted about like toys. The finest engine on the coast furnishes the power—a Corliss engine of 160 horse-power, built in Sacramento.

A blacksmith-shop 60 x 150 ft., to contain 30 forges and three steam-hammers, completes the list of buildings now erected.

Railways in New York.—The report of the State Engineer and Surveyor of Railroads for the last half year, gives the following statistics, which may be interesting to your readers:—

There are fifty-six different railways in operation in the State, the aggregate length of which is 3,053.95 miles, and which have been constructed and equipped at a cost of $208,185,782. Including roads contemplated, the whole number is eighty-one, with a length of 4, 567.99 miles. The oldest line is the Mohawk and Hudson, opened for travel a distance of seventeen miles, in 1831. The number of locomotives in use is 1,111; passenger cars, 1,163; baggage and mail cars, 362; freight cars, 17,934. During 1868, the number of passengers of all classes carried over the State was 18,434,300, and the amount of freight 11,961,692 tons. The cost of operating the roads was $15,250,716; the total payments, $48,274,476; and the total earnings, $49,-377,790. The average rate of speed of ordinary passenger trains, including stoppages, was 18.55 miles per hour, while the average speed of express trains was 29.74 miles. The number of persons killed during the year was 302, and the number injured 358. Of these 104 were killed on the New York and Erie road, out of 2,194,348 passengers carried; on the Hudson River road 27 to 2,626,303; on the New Haven road 6 to 2,192,940; on the Harlem road 20 to 1,667,578; on the Long Island road 4 to 823,000; on the Staten Island road 1 to 349,853. The total amount recovered as damages for injuries to passengers, which the various companies were obliged to pay during the year, was $528,310. The Erie road paid $198,135; the Hudson River Company, $20,745; the New Haven road, $10.937; the Harlem road, $7,865; the New York Central, $72,944; the Buffalo and Erie road, $196,-405.

Steel Fire Boxes for Locomotives.—At the late Master Mechanics' Convention, held at Pittsburgh, a committee was appointed to investigate and report on the question :

Are steel plates preferable to the best iron plates? and if so, does the difference in strength, safety and durability, justify the difference in cost? Also, how, in practical experience, does steel for furnaces compare with copper?

The committee reported much interesting testimony bearing on the subject, among others, the statement of an officer of the Northwestern R. R., who said :

Fifty-one locomotive fire-boxes, made of copper sheets half an inch thick, after thirty months' use, show marked indications of wear, and will probably have to be renewed in a short time. In some cases, after less than three years' service, the original half-inch sheets were reduced to less than one-eighth of an inch.

With reference to the application of steel for the purpose indicated, it was further stated by the same party, that :

On the Northwestern road, a locomotive has been run for eight years with a steel fire-box, which has thus far shown no signs of wear, although the coal and water used had proved extremely detrimental to the iron and copper fire-boxes previously used on the same division of the road.

On the Pennsylvania road, two locomotives fitted with steel furnaces in 1861, still remain intact, and two locomotives on the Baltimore and Ohio, furnished in like manner about the same time, show similar results. The committee unanimously and emphatically concluded "in favor of *homogeneous steel plates* for locomotive fire-boxes, at least of all those that burn bituminous coal; and that for boiler-plates for general construction, this material combines in a greater degree than any other, the requisites of durability, safety and economy."—*Chicago Railway Review.*

The Louisville Bridge.—The great railway bridge on the Ohio river, at Louisville, Kentucky, will be ready for the passage of trains by the end of the present month. It is one of the finest and most important structures of the kind in the country. Its total cost when complete will be about one and one-half million of dollars. The length of the bridge is 5,200 ft., or nearly a mile. It is supported by twenty-five massive piers. The longest span is over the middle chute, and is 370 ft. At this point the bridge is $90\frac{1}{2}$ ft. above low water mark. There is a drawbridge over the canal of $114\frac{1}{2}$ ft. clear span. The grade from the Kentucky side is 82 ft. to the mile, the grade on the Indiana side being nearly 79 ft. A long and heavy embankment is necessary on the west side of the river, and that is nearly done. This bridge in addition to its railroad uses, is built for street cars and wagons, the supposition being that at certain times of the day—only one-eighth of the twenty-four hours—the railroad trains will occupy the bridge, leaving it free the rest of the time for ordinary travel. The estimates of this grand structure tell the story of what it is. The masonry cost $476,962, the iron superstructure $776,090, the whole amounting to $1,600,000.—*Polytechnic.*

Long Railway Running.—In a recent article we referred to several instances of continuous railway "runs" of from 76 to $97\frac{1}{2}$ miles. We should have instanced the mail trains on the South-Eastern line, which, on the old line made 88 miles without stopping. *Via* Sevenoaks, the distance, we believe, is 75 miles. The engines have 16 in. (some of them 17 in.) cylinders, 22 in. stroke, and a single pair of 7 ft. driving wheels. The tenders contain 2,500 gallons of water. The usual train is from fourteen to eighteen carriages, and the average speed is from 40 to 45 miles an hour.—*Engineering.*

A Remarkable Railroad.—The most remarkable railroad in Germany and Europe is the new Black Forest road, which will be completed within four years. Between Hornberg and St. George, situated 2,870 feet above the level of the sea, and but four miles distant from Hornberg, the railroad ascends nearly 2,000 ft., and passes through 27,000 ft. of tunnels. Eleven thousand feet of the latter have been completed during the last two years. The truly cyclopean work on the road is progressing rapidly, and attracting thousands of visitors, who flock there from all parts of Southern Germany and Switzerland.—*Polytechnic.*

NEW BOOKS.

Useful Information for Railway Men. By W. G. Hamilton, Engineer. D. Van Nostrand, 23 Murray street, New York.

We can fully indorse the following notice of this excellent work from "Engineering:"

This pocketbook, which in its original form and first edition was intended to serve no other purpose than a useful advertisement, has in its second issue developed into a *vade mecum*, which will be found more comprehensive and more serviceable than any work of the same kind in existence. The author, Mr. W. G. Hamilton, who is the manager of the Ramapo Wheel and Foundry Company, an establishment but recently established, yet now doing almost the largest business in chilled cast-iron wheels in the United States, contemplated originally the compilation of such a pocketbook from existing works of the same nature, and supplemented by his own notes and those of some other American engineers, as would be compressed into a small volume, that would carry its own recommendation as well as that of the business for which it served as an advertisement. This edition, which was a very large one, was gratuitously circulated throughout the United States, and led to so large a demand that the author determined upon producing a second edition, in which the Ramapo Foundry should make no obtrusive appearance. This is the issue under notice. It consists of 569 pages of very closely printed matter, in which are contained the bulk of Molesworth's, Hurst's and Nystrom's pocketbooks, copious compilations from the principal scientific writers, and, above all, a large compendium of United

States' railway practice. Of course a great deal of its contents have a special value for the American engineer, but these notes recommend themselves most strongly to ourselves, as representing the latest and best practice in the States. The index contains nearly a thousand items, many of which are illustrated sufficiently well to explain fully the subject to which they refer. The extent, cost and general particulars of American railways are given, the standard specification of rails upon the principal railways, the dimensions and description of rolling stock, the most recent improvements in locomotive practice, and epitomes of the financial management of railways. It would, of course, be impossible to convey an idea of the almost endless subjects upon which this little book touches, in each case profitably: it must suffice to recommend it, and to trust that it may be placed within the reach of English engineers.

The Polytechnic.—A Semi-monthly Paper devoted to the interests of Polytechnic and Scientific Schools, and a Record and Review of Civil, Mechanical and Mining Engineering, Natural Science and General College News, Troy, New York. Montague L. Marks, Editor and Proprietor.

We can best state the character of this excellent publication by quoting from its prospectus:

"In adopting the name Polytechnic, our design has been two-fold, viz: First, to identify closely the title of our publication with that branch of knowledge, to the advancement of which it is especially devoted; and Secondly, by the general significance of the name as applicable to all Polytechnic and Scientific Schools, to demonstrate the design of the publisher to make the Polytechnic their common mouthpiece. By arrangements that we have made with some of the most able contributors to scientific periodicals in this country, and with other gentlemen of known ability, in each issue of the Polytechnic will be found valuable and original articles on subjects of general scientific interest. We shall devote a portion of our columns to items of current general scientific news selected and condensed from the best American and European papers and magazines. We have established a corps of correspondents at the various Polytechnic and Scientific Schools, and at the Scientific Departments of the principal Colleges, and from them we shall receive news on all topics of interest connected with their several localities."

We can assure our readers that the Polytechnic answers fully to this specification. And it is perhaps more elegantly "got up" than any other American scientific publication.

A Treatise on Land Surveying, in theory and practice, giving the best methods of surveying and leveling, for statistical, estate and engineering purposes, together with full explanations of the construction, adjustment and use of theodolites, levels and other instruments required in the field and office work of surveying and leveling. By John A. Smith, Civil Engineer, London. Longmans, Green & Co., 1869. For sale by Van Nostrand, New York.

This work is well spoken of by the "Mechanics Magazine," which says:

While on the one hand the author has to travel a good deal in a well-worn path, it is open to him on the other to strike out a few fresh branches, without actually deviating from the main line. He has availed himself of this opening, and also treats the whole subject in that advanced style of mathematical and geometrical investigation which it is now able to bear. In former times, surveyors as a rule, were not educated men in any sense of the term, and a book similar to the one under notice, would not have been appreciated as it deserves to be. At the same time it must not be imagined that the author has plunged into the regions of abstruse mathematics. On the contrary, the formulæ and rules he gives are of a simple and practical nature, and may be easily mastered by any one possessed of that moderate amount of algebraical knowledge which all professional students acquire as a matter of course.

An International Floating Tunnel. By E. W. Young, C. E. London, E. & F. Spon, 1869. For sale by Van Nostrand.

In the plan laid down by the author, it is proposed to construct between Dover and Cape Gris-Nez, a wrought-iron tunnel, in sections of from 200 to 300 ft., to float these into position and lower them into place at a certain depth below the surface of the water, where the joints being made good by divers, they would form one continuous tube across the Channel. Mr. Young thinks that the tube being buoyant it would have to be held down to the proper depth by means of anchor-chains attached to huge blocks of béton. The passage of trains would not materially affect the buoyancy, and the tube being placed below the surface would not be injured by the violence of the waves. Air would be supplied by a number of lighthouses placed along the line of the tube. Numerous sections and illustrations accompany Mr. Young's description, but we fear that his ideas will not receive the support of practical men. We think he underrates the difficulty of submerging and repairing such a tube as that he contemplates, and that he likewise insufficiently considers the terrible influence of the tidal currents on so large a mass.—*Scientific Opinion.*

Society of Engineers' Transactions for 1868.—Spon, 48 Charing-cross. For sale by D. Van Nostrand. 23 Murray street, New York.

In the volume of this Society's Transactions just published, abundant proofs are evident of the increased care bestowed upon it by its editor. The volume contains nine papers, the three first of which by Dr. Edward Cullen, may be classed as one, belonging, as they do, to the same subject—improved communication between the Atlantic and Pacific, *via* the Isthmus of Darien. A paper on Engineering in India, by Mr. C. F. Danvers, and several minor contributions, brought the session nearly to a close, its two final meetings being occupied by Mr. Baldwin Latham's elaborate paper on Steam Cultivation, in which he deals as exhaustively with his subject as he did in his inaugural address, where sewage formed the *pièce de resistance*. To Mr. Latham and to Dr. Cullen, the volume owes the bulk of its handsome collection of finely executed lithographs.—*Engineering.*

A Text Book of Chemistry. A Modern and Systematic Explanation of the Elementary Principles of the Science, adapted to use in High Schools and Academies. By Le Roy C. Cooley, A. M., etc. New York, Charles Scribner & Co., 1869.

THE PRINCIPLES OF PERSPECTIVE ILLUSTRATED IN A SERIES OF EXAMPLES. By HENRY D. HUMPHRIS. Descriptive Treatise and Atlas of Examples. London: Chapman & Hall. 1869.

Mr. Humphris, who is the son of an architect well known in his locality, has issued what is rather a series of examples to illustrate the principles of perspective than an elaborate essay on the science. They are drawn out of good size, and will be found very useful to art-masters, architectural students, and others. Mr. Humphris rightly points out that it would be useless to read the letter-press and look at the plates, and to imagine that a knowledge of perspectives is to be obtained by any such means; while to copy the figures line for line from the examples would be time as badly spent.—*The Builder*.

FIVE HUNDRED AND SEVEN MECHANICAL MOVEMENTS. By HENRY T. BROWN, Editor of the American Artisan. New York, Virtue & Yoston. For sale by Van Nostrand.

The public attention has been largely called to the book, but until every artisan, and especially every mechanician possesses it, we do not think too much can be said of its value. It consists simply of engravings and descriptions of 507 methods of transmitting or changing motion and power, in all the departments of mechanical construction, and running through every variation and combination of the mechanical powers, in gearing, escapements, water wheels, hydraulic machines and miscellaneous machinery. It contains a great many facts and a very little preaching, which is the best thing we can say of any book.

SPECTRUM ANALYSIS.—Six lectures delivered in 1868, before the Society of Apothecaries of London. By HENRY E. ROSCOE, B. A., Ph. D., F. R. S., Professor of Chemistry in Owen's College, Manchester. London, Macmillan & Co., 1869. For sale by Van Nostrand.

It was time that the general public should be made familiar with the grand facts and principles of spectroscopic analysis, and we therefore at the outset publicly thank Professor Roscoe for coming forward as the interpreter between the student of science and the educated members of the community. He has taken upon himself a task whose importance is only equaled by its difficulty, and it is only just to him to express our opinion that he has discharged a complex duty with ability and success. —*Scientific Opinion*.

A MANUAL OF THE HAND LATHE. Comprising concise directions for working metals of all kinds, ivory, bone and precious woods; dyeing, coloring and French polishing; inlaying by veneers, and various methods practiced to produce elaborate work with dispatch and at small expense. By EGBERT P. WATSON, late of the Scientific American, author of "The Modern Practice of American Machinists and Engineers." Illustrated by 78 engravings. Philadelphia, Henry Carey Baird, Industrial Publisher, 406 Walnut street. Price $1.50.

A POPULAR OUTLINE OF PERSPECTIVE OR GRAPHIC PROJECTION; PARALLEL, DIAGONAL, PANANGULAR, GRACEFUL. By THOMAS MORRIS, Architect. London: Simpkin, Marshall & Co. 1869.

THE STEPPING-STONE TO ARCHITECTURE. By T. MITCHELL. London, Longmans, Green & Co.

RAILWAY ECONOMY: USE OF COUNTER-PRESSURE STEAM IN THE LOCOMOTIVE ENGINE AS A BRAKE. By M. L. LE CHATELIER, Ingénieur-en-Chef des Mines. Translated from the author's manuscript by Lewis D. B. Gordon, F. R. S. E., Honorary Member of Institution of Engineers in Scotland. Edinburgh, Edmonston & Douglas.

THE ELEMENTS OF BUILDING, CONSTRUCTION AND ARCHITECTURAL DRAWING. By ELLIS A. DAVIDSON. London and New York, Cassell, Petter & Galpin. For sale by Van Nostrand.

MISCELLANEOUS.

SURFACE CONDENSER TUBES.—Rolled sheet copper is now quoted at about 80*l*. per ton, equal to a little more than 8½d. per pound, although the nominal quotation *by the pound*, is 10d. Solid drawn copper condenser tubes of from ½ in. to 1 in. in diameter, and sold only by the pound, are, on the average 1s. 10d. per pound, showing a charge of at least 1s. per pound, or more than the value of the metal itself, for the mere process of drawing—a process as tedious as it is trying to the metal. The usual thickness of these tubes is No. 18 of the Birmingham wire gauge, or one-twentieth of an inch. By the old process of drawing it would not be safe to make them much thinner on account of the risk of their splitting, the very process of drawing inducing longitudinal weakness, a weakness not found either lengthwise or widthwise of rolled copper sheets. Copper of No. 18 gauge weighs about 2 lbs. 6 ozs. per square foot, and as a foot of ⅞ in. tube would require one-quarter of a square foot of plate, it works out that 2⅜ lbs. of copper would make four lineal feet of such tube, costing from 1s. 9d. to 2s. for metal, and selling for 4s. 4d. equal to a charge of from 7d. to 8d. per foot for drawing alone.

But copper of No. 18 gauge is only employed because of the risk of drawing it thinner. No. 23 gauge, of but half the thickness, and therefore of but half the weight, would be abundantly strong for a small surface condenser tube withstanding but 25 lbs. or, at the most 30 lbs. pressure per square inch, whereas its full strength, if sound, should be equal to an internal pressure of at least a ton per square inch. Yet with No. 18 tubes, which *ought* to withstand two tons per square inch, the highest test pressure adopted by some of our leading marine engineers is but 60 lbs. per square inch. And this is enough, being at least twice what the tube ever has to withstand. If the tubes could be made of half the thickness, that is, No. 23 of the Birmingham wire gauge, they would conduct heat even more rapidly than when of No. 18 gauge, and thus even less condensing surface, and, therefore, even less than half the weight of tubing would be requisite.

But the cost of drawing, viz: 7d. to 8d. per foot, is in itself enormous. The tube machine exhibited at Messrs. Robert Stephenson & Co.'s works during the Newcastle meeting of the Mechanical Engineers, and now again working, we believe, at Messrs. George England & Co.'s works at Hatcham, can convert sheet metal into tubes at a cost, for manufacture, not exceeding half a farthing per foot. The joint made is a mechanical joint only, but it has been tested to more than three times the proof test we have named, and that without the slighest suspicion of a leak. With the success, already reasonably certain, of this mode of making tubes, it will be matter of surprise, if ¾ in. condenser tubes, now costing 13 d. per foot, are not brought down to 5 d. No combination of the simplest mechanical movements has for a long time been announced with any claim to the genuine merits of the American machine.—*Engineering.*

TELEGRAPH ENTERPRISE.—The disposition of the public to pay attention to telegraphic enterprise is attended by the usual result of a multiplicity of projects being hurried out, but the events of 1866 are not yet sufficiently remote to admit of the prospect of danger. The French Atlantic cable being only a few weeks old, a new one from Ireland to Nova Scotia of a light description, to cost £450,000, is now talked of, which is to do the work of the existing cables at half-price. If the capital could be found and the line successfully laid, the shareholders would probably be informed within a month that a fresh one of still lighter construction would be proposed, which, at a further reduction of 50 per cent in the tariff, would still be expected to prove highly remunerative. That the progress of electrical science will ultimately cause the cables of the present day to appear cumbrous can hardly be doubted, but much further experience will be necessary before any very costly experiments in that direction can be ventured upon. It is affirmed on good authority that during the last eighteen years there have been 8,000 miles of light cable laid, some covered with light wire, two consisting of india-rubber core alone, and others protected with hemp and other substances, but that no line of this description has been found to last longer than one year, while in some cases the period has been a few weeks only. All the cables now in working order are of the strong and heavy form, and there seems no example of any kind that can be cited to justify the adoption of the light principle.—*London Times.*

THE OXYHYDROGEN LIGHT scheme has now taken a definite shape in Paris. A company has been formed, the capital necessary has been raised, and application has been made for permission to lay down pipes to carry oxygen and hydrogen over about a fourth of the city. It is not very likely that the permission will be granted, and the promoters will have to confine themselves to supplying individuals with compressed gases, as was originally proposed. We have published the patented processes by which M. Tessié du Motay obtains the oxygen and hydrogen which he proposes to distribute over Parris, at a cost so low that the oxyhydrogen light is promised much cheaper than common gas light; but ingenious and relatively cheap as they undoubtedly are, it is impossible to believe that the service can be made so inexpensive as to supersede coal gas. The prospectus of the company enlarges upon the cheapness and purity of the light, the complete combustion, and the absence of all deleterious matters in the products of the combination; but is quite silent as to the danger of introducing into a house two gases not possessing any smell, and which, consequently, may escape without observation, and the mixture of which forms an explosive compound of far greater power than any mixture of coal gas and air. To any danger of this kind, Continental engineers appear to shut their eyes. We saw, a short time ago, a patent taken out in Belgium for making a mixture of coal gas and air, storing it in gas holders and distributing it over the city of Brussels for heating purposes. The engineering details given, showed a complete knowledge of the subject of the manufacture and distribution of gas, but there seemed to be no recognition of the risk, imminent enough of blowing up the whole concern. A consideration of this kind, some years ago, stood in the way of a scheme of the kind projected for Birmingham, and will, no doubt, prevent the Oxyhydrogen Light Company from getting permissson to lay down their pipes over Paris.—*Jour. Franklin Institute.*

TINTS TO EXPRESS BUILDING MATERIALS.—The following are the conventional tints employed in England, and with little exception, elsewhere among engineers and architects:

Materials.	Color.
Brickwork to be executed (in plans and section..	Crimson lake.
Brickwork in elevations..	Crimson lake mixed with burnt sienna or Venetian red.
The lighter woods, such as fir................	Raw sienna.
Oak or teak............	Vandyke brown.
Granite	Pale Indian ink.
Stone generally.........	Yellow ochre or pale sepia.
Concrete works.........	Sepia with darker markings.
Wrought iron	Indigo.
Cast iron	Payne's grey or neutral tint.
Steel..................	Pale indigo tinged with lake.
Brass	Gamboge or Roman ochre.
Lead	Pale Indian ink tinged with indigo.
Clay or earth..........	Burnt umber,
Slate..................	Indigo and lake.

THOMSON'S ROAD STEAMERS.—The Oriental Coal Company (Limited), into whose hands the extensive coal mines in the island of Labuan have passed, are now working them successfully. In anticipation of a great increase in the demand for coal in the China seas on the opening of the Suez Canal, it has been decided to supply coal at the fine harbor of Victoria, which admits and shelters vessels of the largest size at all times of the tides and at all seasons, instead of at Coal Point, as at present, where steamers can take in coal only in comparatively fine weather. The distance from the mines to Victoria harbor, where the Governor's residence and all the public buildings are situated, is about nine miles, and the coal is to be transported by means of the patent road steamers, with india-rubber tyres, of Mr. R. W. Thomson, C. E., of Edinburgh. Two of these powerful engines and sixteen wagons, to carry six tons each, are already completed, and will be shipped direct to Labuan in the company's new screw collier "the William Miller." These road steamers appear to be exciting great interest all over the world. The Government of India have just ordered to be despatched overland the first engine for a regular service, which they intend establishing on the Grand Trunk Road, for the transport of troops, Government stores, and general merchandise, in lieu of the miserably slow and costly bullock-trains which now creep along that fine road. The road steamers will, it is said, run five or six miles per hour at far less cost than the bullock hackeries, which cannot keep up a third of that speed.

To estimate the force of the tides, all that is necessary is the consideration that the attraction of the sun and moon (principally of the latter), acting in opposition to terrestrial gravitation, elevates the surface of a large portion of the ocean, nearly twice in 24 hours, to the mean height of about two feet. The extent of surface thus raised may be set down at 100,000,000 square miles, or one-half of the surface of the earth, taking this at 200,000,000 of square miles, of which the ocean occupies about three-fourths, or 150,000,000. Every square mile o water two feet thick contains nearly 60,000,000 ubic feet, or 3,840,000,000 pounds of water, an this, multiplied by 100,000, 000, the number of square miles affected by the tide, gives the enormous number of 768,000,000, 000,000,000 foot pounds exerted every twelve and a-half hours, or 7 minutes, which gives, per minute, a power o 100,000,000,000,000,000 foot pounds. Dividing is by 33,000, to reduce it to horse-power, we obain nearly 3,000,000,000,000 horse-power as the total power of the tide-wave over the whole sufa of the earth.—*The Engineer.*

Zinc Sheathin or Ships.—There is nothing novel in the le of preventing the oxidation of iron ships by h use of zinc. Several modes of applying the ac have been suggested by various inventive mls but, for some reason or other, shipowners still y on paint to preserve their ships, and do not se to have faith in the protective power of elecal action. The latest invention for the protec of iron ships by this means is that of MM. Dunce and Bertin, who distribute about the inner e of the shell, tubular reservoirs, made of zinc, ich are riveted to the plates, to place the meta perfect communication with the iron hull. Th reservoirs are charged with sea water, which is nged every day. Bands of zinc carried in all dtions over the inner side of the hull connect thrious reservoirs, and strips are here and there ight to the outer side, and made to communicat th the sea. We need not here explain the actwhich takes place. If the authors can be relioon, the success obtained is perfect. Experimal boats kept in very salt water for a year, they, do not exhibit a trace of oxidation in any —*Mech. Magazine.*

Apprentice em in the shops of the Pennsylvania lway.—Of the 4,087 names on the rolls of thtive Power and Mach. Dept. at the beginninghe year, 114 are designated as "apprentices." to these we were to add such as among the thousand skilled workmen have risen to that chrough apprenticeship, the number would be ised perhaps three-fold or more. Boys are take eventeen years of age,—if possible on their i-day,—and are indentured for four years, recg 75 cents per day for two years, 90 cents the tlear, and $1,00 the fourth. If during this peif apprenticeship their conduct and service leen satisfactory, they receive $124 bonus on the cancellation of the indenture. They afterwards receive, as skilled workmen, from $1,50 to $2,90 per day. Work begins in the locomotive shops with vice-filing, from which the apprentice passes, successively to machine work, running tools, and setting up engines; in carpentry, freight is followed by passenger car work. The result is, in the case of a boy adapted to the work, not only skill in the performance of the different operations involved in car or locomotive building, but a discipline, a system, which admirably fit him to take charge of work; and, accordingly, we find that many of the best foremen, to whose inventiveness and resources the Company owes much every year, are from the class of apprentices who have received technical education in the shops. The system works satisfactorily in every respect. It is sometimes the case that the apprentice, now become an expert, seeks service elsewhere at the end of his term; but with rare exceptions, such return in the course of a year or two.—*Chicago Railway Review.*

The Albany Iron Works' Axles.—The car axles made by Messrs. Erastus Corning & Co., and which have deservedly attained to a great celebrity on the many railways where they are used, are made as follows: Selected scrap or selected puddle-bar made from charcoal (20 per cent) and best anthracite pig, is rolled into 2 by 1 in. bars. These bars are made into a pile 8 in. square with ¾ in. top and bottom made of finished bars. The pile is reheated and rolled to 7 in. round, and this is reheated, forged down and finished under the trip hammer. It is not surprising that these axles never break in service.

Our Index.—Those who have occasion to refer to the back volumes of Engineering periodicals, will admit that, as a rule, the easiest way to find any given article is to begin at page 1 and search for it. Index making has been deemed merely clerical work, as if no professional knowledge were necessary in arranging subjects under the proper headings. We believe the index presented herewith will be found convenient and complete.

The India Rubber Manufacture.—The *North American Review* states that there are now in America and Europe, more than a hundred and fifty manufactories of india-rubber articles, employing from four to five hundred operatives each, and consuming more than ten millions of pounds of gum per annum. The business, too, is considered to be still in its infancy. Certainly it is increasing. Nevertheless there is no possibility of the demand exceeding the supply. The belt of land around the globe, five hundred miles north and five hundred miles south of the equator, abounds in trees producing the gum; and they can be tapped, it is said, for twenty successive seasons. Forty-three thousand of these trees have been counted in a tract of country thirty miles long and eight wide. Each tree yields an average of three tablespoonfuls of sap daily, but the trees are so close together that one man can gather the sap of 80 in a day.

Lighthouses.—According to the *Scientific Review*, a French writer calculated that, at the commencement of 1867, there existed in the world 3814 lighthouses, or phares, of more or less importance, viz: 1785 on the coast of Europe; 674 on those of America; 162 in Asia; 100 in Oceania; and 93 in Africa. As regards Europe, the best lighted coasts are those of Belgium, France following immediately afterwards. Then come, in order in which their names are given, Holland, England, Spain, Prussia, Itlay, Sweden and Norway, Portugal, Denmark, Austria, Turkey, Greece, and finally Russia. Besides Europe, the best lighted coasts are those of the United States, which have one light for every twenty miles, whilst the Brazilian coast has only one for every 87 miles. Of the 2814 in existence at the commencement of 1867, about 2300 had been established since 1830, while the power of the greater part of those existing prior to 1830 has increased.

The Steamship Adriatic.—This fine American built vessel has been purchased by Messrs. Bates & Co., of Liverpool, for the purpose of being converted into a sailing ship. The Adriatic was originally one of the Collins' line of mail steamers, and ran for a time between Liverpool and New York. In 1861 she was purchased by the Atlantic Royal Mail Company, and in the month of April of that year was placed on their line between Galway and New York. Towards the end of 1861 she was chartered by the government to convey troops to Canada, and on her return she was again fitted up as a passenger ship and placed on the Galway line until the whole undertaking collapsed, when she was taken round to Southampton Docks, where she has remained unemployed until the present time. The Adriatic is one of the largest paddle steamers ever built, and her history has been anything but an uneventful one. She was built and fitted up at enormous expense, and now, after lying idle for six years, she has changed hands at very little more than her repairs and fittings have cost. She will make a magnificent sailing vessel, although not adapted for the Atlantic steam trade.

Oroide is the name of a new metallic composition which resembles gold very closely. It was invented in France, and is made by means of 100 parts of copper; 17 parts of tin or zinc; 6 parts of magnesia; 3-6 parts of sal-ammoniac; 1-8 parts of calcined lime and 9 parts of cream of tartar. The copper is at first melted alone; then magnesia; sal-ammoniac; lime and cream tartar are added in small portions under continual stirring. This takes half an hour, then tin or zinc is added, and mixed with the copper by stirring. The crucible in which these operations are prepared, is then covered up and kept in the fire for 35 minutes. The product is cast into bars, which can be rolled, hammered and pressed. It is difficult to distinguish this composition from gold.—*Steirm. Industrie u. Handelsblatt.*

The Vacuum Method of Making Ice.—An ice and cold producing machine has been invented by Herr Franz Windhausen, Brunswick. The action of the machine is based on the principle of producing cold by the expansion of atmospheric air, which is accomplished by means of mechanical power. The machines require no chemicals, nothing being used in them but water and atmospheric air. They may be wrought by steam, water, or wind, and they produce from 100 to 1,000 lbs. of ice per hour, according to size, at a cost of from 2d. to 5d. per 100 lbs.; this difference resulting from the varying prices of fuel and the mode of working chosen. One of their uses is to cool rooms, cellars, theaters, hospitals, compartments of ships, etc.—*Builder.*

The Smoke Nuisance.—Dr. Angus Smith has experimented on smoke of various degrees of blackness and brownness, and he shows that the difficulty of consuming smoke does not commonly arise from a deficiency of air in the furnace, but from the fact that a rapid draught often fails to allow time for proper combustion. It is now certain that the black smoke prohibited by Act of Parliament contains carbonic oxide, one of the most poisonous of gases. Carbonic oxide is only detected in smoke of the illegal density, and when we find that this black smoke is really an expensive article to produce we seem to be furnished with every reason why such a nuisance should be prohibited.

The Bermuda Floating Dock.—Although predictions of disaster as to her voyage out were plentiful, the great Bermuda dock has arrived safely at the island. The passage was made, it would appear, under favorable circumstances. The absence of suitable dock accommodation at Bermuda has long been felt, and now that this want has been so well supplied, war ships on the North American and West India stations can be overhauled and repaired, instead of being sent home for those purposes.

The Wire Tramway Com.ny have contracts at present in execution in France for about 25 miles of wire tramway, all f beet sugar makers. Mr. Hodgson, the inventor, is at present engaged constructing the line for the estaena Company in the Alps; besides this, the compy have contracts in Spain, Sweden and Austria, and are shipping lines to New Zealand and Peru. Several short lines are in course of construction England, and the difficulty of obtaining right way is alone preventing them doing a large siness in this country.

Shape of Screw Taps.—Mr. W. A. Sweet of Syracuse, informs us, referring an article we translated on page 976, from a German Magazine, that he commenced a lathe for the e purpose in 1864, that he then learned that Mes Wm. Sellers & Co. had the same idea, and the e has quite recently seen at the works of Messrs enyon & Co., Steubenville, O., a lathe for cutti taps on this principle, made thirty years ago, in use ever since. In this lathe, however, groove has a curved bottom which will not c-a great improvement on the German idea.

The Largest Span of any truridge in the United States is that of the gridge across the Ohio river at Louisville, whic destined to connect the Kentucky and India hores. The bridge itself will be, when finished the engineer in charge expects to turn over contract for the building some time in Novem, one of the most splendid structures of the k this or any other country. This last span c three hundred and seventy feet, and is a ma f engineering skill.—*Engineer.*

British Steam Vessels.—An cial return shows that down to the 1st uary, 1869, there had been registered at the p the United Kingdom 2,916 steam vessels, the egate registered tonnage being 904,191 tons their gross tonnage 1,341,106 tons. The dat uild ranges from 1823 to 1868; the oldest is And Jane, of Newcastle, of 27 tons.
